International Agency for Research on Cancer

The International Agency for Research on Cancer (IARC) was established in 1965 by the World Health Assembly, as an independently funded organization within the framework of the World Health Organization. The headquarters of the Agency are in Lyon, France.

The Agency has as its mission to reduce the cancer burden worldwide through promoting international collaboration in research. The Agency addresses this mission through conducting cancer research for cancer prevention in three main areas: describing the occurrence of cancer; identifying the causes of cancer, and evaluating preventive interventions and their implementation. Each of these areas is a vital contribution to the spectrum of cancer prevention.

The publications of the Agency contribute to the dissemination of authoritative information on different aspects of cancer research. Information about IARC publications, and how to order them, is available at http://publications.iarc.fr/.
In 1969, the International Agency for Research on Cancer (IARC) initiated a programme on the evaluation of the carcinogenic risk of chemicals to humans involving the production of monographs of critical reviews and evaluations of individual chemicals.

The *IARC Handbooks of Cancer Prevention* complement the *IARC Monographs*’ evaluations of carcinogenic hazards. The objective of the programme is to coordinate and publish critical reviews of data on the cancer-preventive effects of primary or secondary interventions, and to evaluate these data in terms of cancer prevention with the help of international working groups of experts in prevention and related fields. The lists of evaluations are regularly updated and are available at [http://handbooks.iarc.fr/](http://handbooks.iarc.fr/).

This *IARC Handbook of Cancer Prevention* is partly funded by the American Cancer Society (contract ACS #26531) and by the Grant or Cooperative Agreement Number DP004954-05, funded by the United States Centers for Disease Control and Prevention. Its contents are solely the responsibility of the authors and do not necessarily represent the official views of the Centers for Disease Control and Prevention or the Department of Health and Human Services.

NOTE TO THE READER

The *IARC Handbooks of Cancer Prevention* series was launched in 1995 to complement the *IARC Monographs*’ evaluations of carcinogenic hazards. The *IARC Handbooks of Cancer Prevention* evaluate the published scientific evidence of cancer-preventive interventions.

Inclusion of an intervention in the *Handbooks* does not imply that it is cancer-preventive, only that the published data have been examined. Equally, the fact that an intervention has not yet been evaluated in a *Handbook* does not mean that it may not prevent cancer. Similarly, identification of organ sites with *sufficient evidence* or *limited evidence* of cancer-preventive activity in humans should not be viewed as precluding the possibility that an intervention may prevent cancer at other sites.

The evaluations of cancer-preventive interventions are made by international Working Groups of independent scientists and are qualitative in nature. No recommendation is given for regulation or legislation.

Anyone who is aware of published data that may alter the evaluation of cancer-preventive interventions is encouraged to make this information available to the IARC Handbooks Group, International Agency for Research on Cancer, 150 cours Albert Thomas, 69372 Lyon Cedex 08, France, or by email to ihb@iarc.fr, in order that these data may be considered for re-evaluation by a future Working Group.

Although every effort is made to prepare the *Handbooks* as accurately as possible, mistakes may occur. Readers are requested to communicate any errors to the IARC Handbooks Group at ihb@iarc.fr.

1 Working Group Members and Invited Specialists serve in their individual capacities as scientists and not as representatives of their government or any organization with which they are affiliated. Affiliations are provided for identification purposes only.

Each participant was asked to disclose pertinent research, employment, and financial interests. Current financial interests and research and employment interests during the past 4 years or anticipated in the future are identified here. Minor pertinent interests are not listed and include stock valued at no more than US$ 1000 overall, grants that provide no more than 5% of the research budget of the expert's organization and that do not support the expert's research or position, and consulting or speaking on matters not before a court or government agency that does not exceed 2% of total professional time or compensation. All grants that support the expert's research or position and all consulting or speaking on behalf of an interested party on matters before a court or government agency are listed as significant pertinent interests.

2 Michael Bretthauer's research unit has received screening devices free of charge from various companies (and returned them to the manufacturer after the trials) for investigator-initiated and -run screening trials.

3 Josep M. Augé Fradera has received significant research support from the Menarini Group, Sysmex Corporation, and Sentinel Diagnostics.
4 Douglas Robertson is a member of the Scientific Advisory Board of Medtronic. He performs some medico-legal consulting work, particularly on delayed diagnosis of colorectal cancer.
5 Carlo Senore’s institution has received equipment support for research from Covidien (previously Given Imaging) and EndoChoice, and received research support from a joint venture of the Piedmont Region and im3D S.p.A.
Each Observer agreed to respect the Guidelines for Observers at IARC Handbooks meetings. Observers did not serve as Meeting Chair or Subgroup Chair, draft or revise any part of the Handbook, or participate in the evaluations. They also agreed not to contact participants before or after the meeting, not to lobby them at any time, not to send them written materials, and not to offer them meals or other favours. IARC asked and reminded Working Group Members to report any contact or attempt to influence that they may have encountered, either before or during the meeting.

A. GENERAL PRINCIPLES AND PROCEDURES

1. Background

The global burden of cancer is high and continues to increase: the annual number of new cases was estimated at 14.1 million in 2012 and is expected to reach 22.2 million by 2030 (Ferlay et al., 2015). With current trends in demographics and exposure, the cancer burden has been shifting from high-resource countries to low- and medium-resource countries.

Prevention of cancer is one of the key objectives of the International Agency for Research on Cancer (IARC). Cancer prevention can be achieved by primary prevention – aimed at preventing the occurrence of cancer – or by secondary prevention – aimed at diagnosing cancer sufficiently early to reduce related mortality and suffering.

Screening and early clinical diagnosis are the principal instruments of secondary prevention of cancer and a fundamental component of any cancer control strategy. Screening may enable detection of cancer sufficiently early that cure and resulting reduction in mortality and having the disease are realistic possibilities given suitable treatment. Screening for some cancers, such as cervical or colorectal cancer, may also detect precancerous lesions, effective treatment of which can prevent occurrence of cancer.

When screening is planned as part of a cancer control programme, only procedures proved to be effective (see below) should be proposed to the general population. Screening usually requires repeated interactions between “healthy” individuals and health-care providers, which can be inconvenient and costly. Furthermore, effective screening requires an ongoing commitment between the public and health-care providers and has inherent public health costs.

2. Scope

Cochrane (1972) first discussed the concepts of efficacy and effectiveness in the context of health interventions. “Efficacy” was defined by Porta (2008) as “the extent to which a specific intervention, procedure, regimen or service produces a beneficial result under ideal conditions; the benefit or utility to the individual or

WORKING PROCEDURES

The Working Procedures of the IARC Handbooks of Cancer Prevention describe the objective and scope of the programme, the scientific principles and procedures used in developing a Handbook, the types of evidence considered, and the scientific criteria that guide the evaluations. These Working Procedures apply to the evaluation of screening procedures and interventions.
the population of the service, treatment regimen, or intervention. Ideally, the determination of efficacy is based on the results of a randomized controlled trial. In contrast, the related term “effectiveness” was defined by the same author as “a measure of the extent to which a specific intervention, procedure, regimen or service, when deployed in the field in routine circumstances, does what it is intended to do for a specific population; a measure of the extent to which a health care intervention fulfils its objectives in practice”.

The distinction between efficacy as measured in experimental studies and the effectiveness of an intervention at the population level is a crucial one for public health decision-making. Efficacy is a necessary but not sufficient basis for recommending screening. The efficacy of a screening procedure can be inferred if effectiveness can be proven. Screening by a given procedure has sometimes been implemented on the assumption that “earlier is better,” even when no evidence of efficacy was available. If such interventions result in a significant reduction in mortality that cannot otherwise be explained, it can be inferred that the procedure is effective. However, uncontrolled interventions in which individuals are exposed to unknown risks and benefits should be avoided.

In addition, the fact that the effectiveness of a screening procedure may be different in different populations is often overlooked. Even when a screening procedure is effective at the population level, other outcomes, such as harm and costs and the potential for other interventions to achieve equivalent benefits, must be considered. A screening programme must satisfy certain minimal requirements (e.g. acceptability, availability of relevant personnel, facilities for screening, and access to pertinent health services) if it is to achieve the results that have been documented in experimental settings.

3. Objectives

The objectives of the Working Group are:

1. To evaluate the strength of the evidence for the preventive efficacy of a screening procedure;
2. To evaluate the strength of the evidence for the effectiveness of screening interventions in defined populations, taking into account the balance of benefit and harm in target populations;
3. To assess other outcomes related to the procedures, as appropriate.

The conclusions of the Working Group are published as a volume of the *IARC Handbooks of Cancer Prevention*.

4. Meeting participants

Five categories of participants can be present at a *Handbook* meeting:

1. The *Working Group* is responsible for conducting the critical reviews and evaluations. The tasks of Working Group Members are described in detail below. Working Group Members are selected on the basis of: (i) knowledge and experience; and (ii) absence of real or apparent conflicts of interests. They have often published significant research related to the screening strategies being reviewed, and IARC uses literature searches or consults with other experts in-house or externally to identify such experts. Consideration is also given to demographic and gender diversity and balance of scientific findings and views.

2. *Invited Specialists* are experts who also have important knowledge and experience, but have a real or apparent conflict of interests. They are invited when necessary to assist the Working Group by contributing technical knowledge and experience during subgroup and plenary discussions. They may contribute text on issues that do not influence the final
evaluation (see Part B, Sections 1 and 2), or review text prepared by the Working Group. Invited Specialists do not serve as meeting chair or subgroup chair, and do not participate in the evaluations.

3. Representatives of national and international health agencies may attend meetings when their agencies are sponsors of the programme or are interested in the subject of a meeting. Representatives do not serve as meeting chair or subgroup chair, do not draft any part of a Handbook, and do not participate in the evaluations.

4. Observers with relevant scientific credentials may be admitted to a meeting in limited numbers upon previous request. Attention will be given to achieving a balance of Observers from constituencies with differing perspectives. They are invited to observe the meeting and should not attempt to influence it. At the meeting, the overall chair and subgroup chairs may grant Observers an opportunity to raise questions or comments, generally after a Working Group discussion is concluded. Observers agree to respect the Guidelines for Observers at Meetings of the *IARC Handbooks of Cancer Prevention* (available at [http://handbooks.iarc.fr](http://handbooks.iarc.fr)).

5. The IARC Secretariat consists of IARC scientists who have relevant expertise. They participate in all discussions, and may serve as rapporteurs. When requested by the meeting chair or subgroup chair, they may also help draft text, prepare tables, or conduct analyses. They do not participate in the evaluations.

Before an invitation is extended, each potential participant, including the IARC Secretariat, completes the “Declaration of Interests for IARC/WHO Experts” form to identify financial interests, employment and consulting activities, as well as individual or institutional research support related to the subject of the meeting. IARC assesses these declared interests to determine whether there is a real or apparent conflict in relation to the topic under evaluation that warrants exclusion or some limitation on participation role. The declarations are updated and reviewed again at the opening of the meeting. Interests related to the subject of the meeting are disclosed to the meeting participants, as well as on the *Handbooks* website and in the published volume. A declaration of interests form is not required from Representatives or Observers.

The names and principal affiliations of participants are made available on the website of the *IARC Handbooks of Cancer Prevention* ([http://handbooks.iarc.fr](http://handbooks.iarc.fr)) approximately 2 months before each meeting. It is not acceptable for Observers or third parties to contact participants before a meeting or to lobby them at any time during the process. Meeting participants are asked to report all such contacts to the IARC Secretariat.

All participants are listed, with their principal affiliations, at the beginning of each volume. Each participant who is a Working Group Member or an Invited Specialist serves in their capacity as an individual scientist and not as a representative of any organization, government, or industry.

5. **Review and evaluation process**

A different Working Group is responsible for developing each new volume of the *Handbooks*. Approximately 1 year before the Working Group meeting, the screening intervention to be reviewed is announced on the *Handbooks* website ([http://handbooks.iarc.fr](http://handbooks.iarc.fr)) and potential participants are selected by IARC staff as described above (Part A, Section 4).

IARC performs literature searches to compile the relevant bibliography in relation to the topic that will be evaluated. Meeting participants are expected to supplement the IARC literature searches with their own searches of published evidence.

The relevant articles are made available to meeting participants, who prepare preliminary
drafts of the sections assigned to them. The participants are provided with instructions on how these drafts should be prepared, in terms of the outline of text and tables, the length, or any other important considerations. The preliminary drafts undergo in-house and external peer review by Working Group Members and Invited Specialists, and the peer-review comments are sent back to the original author, who revises the draft before the meeting.

The Working Group then meets at IARC for eight days to discuss and review all the drafts and to formulate the evaluations. The objectives of the meeting are peer review, evaluation, and consensus. During the first days, the participants meet in separate subgroups to review the drafts of their specific section(s), develop a joint draft, write summaries of the evidence, and propose preliminary evaluations (as appropriate). Care is taken to ensure that each study summary is written or reviewed by someone not associated with the study being considered. During the last days, the Working Group meets in plenary session to review the subgroup drafts and develop the final evaluations. As a result, the entire volume is the joint product of the Working Group, and there are no individually authored sections.

IARC Working Groups strive to achieve a consensus evaluation. Consensus reflects broad agreement among Working Group Members, but not necessarily unanimity. The chair may elect to poll Working Group Members to determine the diversity of scientific opinion on issues where consensus is not readily apparent.

Thus, the tasks of the Working Group are as follows:

1. Ascertain that all appropriate data have been retrieved;
2. Select the data relevant for evaluation on the basis of scientific quality;
3. Prepare summaries of the data that will allow the reader to follow the reasoning of the Working Group;
4. Evaluate separately the efficacy and the effectiveness of the screening procedure(s).

After the meeting, a Special Report is published in the *New England Journal of Medicine* and a summary of the outcome of the meeting is posted on the *Handbooks* website ([http://handbooks.iarc.fr](http://handbooks.iarc.fr)). Subsequently, the accuracy of the final draft resulting from the meeting is verified by the scientific staff of the *Handbooks* programme, by consulting the original literature, and the volume is edited and prepared for publication. The aim is to publish the full volume within 12 months after the Working Group meeting in both print and digital formats.

6. **Inclusion criteria for data for the Handbooks**

The *Handbooks* do not necessarily summarize or cite the entire body of literature on the intervention being evaluated. Only data considered by the Working Group to be relevant to making the evaluation are included. Epidemiological studies, randomized controlled trials, modelling studies, and meta-analyses published or accepted for publication in the openly available scientific literature are reviewed by the Working Group. The same publication requirement applies to meta-analyses or pooled analyses commissioned by IARC in advance of a meeting (see Part B). Also, reports from recognized national or international agencies that have undergone peer review and that are publicly available are considered. Data judged to be uninformative to the evaluation may, at the discretion of the Working Group, be cited but not summarized. If a group of similar studies is not reviewed, the reasons are indicated (see Part B for details). Meeting abstracts and other reports that do not provide sufficient detail upon which to base an assessment of their quality are not considered. Exceptionally, doctoral theses and other materials that are in their final form and publicly available may be
considered if their inclusion is deemed pertinent to making a final evaluation.

B. SCIENTIFIC REVIEW AND EVALUATION

The available studies are summarized by the Working Group, with particular regard to the qualitative aspects discussed below.

Inclusion of a study does not imply acceptance of the adequacy of the study. Major limitations that impinge on interpretation, or reasons for not giving further consideration to an individual study, are brought to the attention of the reader by the addition of Working Group comments in square brackets.

Studies that are judged to be uninformative to the evaluation are omitted, but the rationale for exclusion should be stated. However, less informative studies may be mentioned briefly when: (i) they provide supporting evidence to that in other studies; or (ii) they provide the only published data available on a specific issue.

The Working Group may conduct additional analyses and use these in their assessment of the evidence. Such analyses are identified by square brackets in the text and tables.

The outline of a Handbook on screening includes the following sections.

1. Descriptive epidemiology and disease characteristics

This section succinctly presents data on the cancer being considered: the global distribution and burden, including regional differences and time trends. Expected trends in the absence of screening are a relevant component of this section. The natural history of the disease and the established risk factors and protective factors are briefly described. Information on treatment and survival in different settings is reviewed, with a worldwide perspective.

2. Screening techniques

Each of the screening techniques to be considered is described in this section. The ability of each procedure to detect cancer and to distinguish cancer from non-cancer conditions is presented:

• Equipment and training to perform the procedure;
• Technical quality control;
• Screening performance, including sensitivity, specificity, or positive predictive value;
• Host factors affecting screening performance.

3. Availability and use of screening practices

An overview of how screening is delivered in different regions of the world is presented in this section, with emphasis on the following aspects:

• Availability of policies and guidelines for screening for that cancer;
• Type of screening provided (opportunistic screening, organized population-wide programme, other screening initiatives); availability of facilities; screening procedures most commonly used or recommended;
• Extent of population coverage and participation rates.

In addition, demographic and behavioural considerations that affect participation in screening are presented in a global perspective, with some local characteristics or specificities as appropriate.
4. Efficacy and effectiveness of a screening procedure

For the evaluation of both efficacy and effectiveness, the Working Group considers the following general principles in making judgments about the available studies:

- Relevance of the study;
- Appropriateness of the study design and analysis to the question being asked;
- Adequacy and completeness of the presentation of the results;
- Degree to which chance, bias, and confounding may have affected the results.

4.1 Efficacy

In this section, evidence from randomized controlled trial (RCT) studies is reviewed. All aspects of study design and analysis are critically discussed. Indicators of the efficacy of the procedure in terms of mortality or incidence, as well as other relevant indicators, such as the detectable phases of the natural history of the disease, are presented.

Aspects that are particularly important in evaluating RCTs are: the selection of participants, the nature and adequacy of the randomization procedure, evidence that randomization achieved an adequate balance between the groups, exclusion criteria used before and after randomization, compliance with the intervention in the screened group, and “contamination” of the control. Other considerations include the means by which the outcome (preneoplastic lesions or cancer) was determined and validated (either by screening or by other means of detection of the disease), the length and completeness of follow-up of the groups, and the adequacy of the analysis.

When RCTs are lacking, efficacy cannot be directly evaluated, but only indirectly inferred from observational studies (see below).

4.2 Effectiveness of population-based screening

The impact of the screening procedure when implemented in defined populations is examined in this section.

In this section, mostly observational studies are reviewed, conducted in settings with organized screening programmes or with opportunistic screening. In cohort studies, particular attention is paid to the length and completeness of follow-up; in case–control studies, particular attention is paid to the definition of cases and controls, and the screening method. In all observational studies, the potential for chance, bias, and confounding is carefully examined.

(a) Beneficial effects

Benefits include a decrease in the incidence of invasive cancer or in cancer-related mortality. In addition, indicators used to monitor effectiveness, such as detection rate, rates of interval cancers, and the number of tests performed, may also be considered. Studies of time trends before and after implementation of screening, as well as comparisons, including geographical comparisons, of the occurrence of the disease and death from the disease in populations exposed and not exposed to screening may also be reviewed and interpreted when relevant. In doing this, the Working Group takes into account differences in screening procedures (e.g. frequency and the age of the target population) and of participation rates.

When appropriate, the extent to which improved treatment has been responsible for any observed changes in mortality should be considered in assessing the evidence for effectiveness.

Compliance with participation in screening by a given procedure will also be considered as part of the evaluation of the effectiveness.
(b) Adverse effects

Adverse effects to individuals that are linked to the screening procedure are also reviewed. Evaluation of harms includes estimates of rates of false-positive and false-negative findings and their consequences in screened individuals, overdiagnosis, and interval cancers. Harms may also include screening-related medical complications or discomfort, or psychological effects such as anxiety induced by undergoing screening. The rates of short- and long-term adverse effects of the screening procedure and the likelihood of unnecessary treatment are discussed. Evidence on adverse effects may come from any type of epidemiological study design, including RCTs, observational studies, or other studies as relevant.

(c) Harm–benefit ratio and cost–effectiveness

Evidence for the harm–benefit ratio and the cost–effectiveness of the screening procedure in various settings is considered, mostly from modelling studies. The discussion takes into account the costs per case detected and the benefits per death prevented. Modelling studies will be reviewed similarly to other studies, with particular attention paid to assumptions.

5. Summaries

This section presents summaries of the data reviewed in Sections 1 to 4, providing the key evidence and the rationale leading to the evaluations, as well as important outcomes/findings for which no formal evaluation is conducted. This section is the most read chapter in the entire Handbook. For this reason, it is essential that it provides the background and rationale of the Working Group’s evaluation, yet remains concise and understandable to non-specialist readers. The summary should not contain studies or data that are not mentioned in the main text or tables, or that have been considered uninformative by the Working Group. Technical jargon should be avoided, and no references will be cited in the final version.

In the case of limited or inadequate evidence, the Working Group should highlight, in the form of a rationale, those aspects of the procedure for which information is lacking and which led to the uncertainty in evaluation.

6. Evaluation

For each screening procedure considered, a separate evaluation of the degree of evidence for efficacy and for effectiveness is formulated according to the following definitions.

- **Sufficient evidence for the efficacy or for the effectiveness of screening by a given procedure** will apply when screening by this procedure is consistently associated with a reduction in mortality from the cancer or a reduction in the incidence of invasive cancer, and chance, bias, and confounding can be ruled out. In addition, for the evaluation of effectiveness, the balance of benefits and harms has been taken into account.

- **Limited evidence for the efficacy or for the effectiveness of screening by a given procedure** will apply when screening by this procedure is associated with a reduction in mortality from the cancer or a reduction in the incidence of invasive cancer, or a reduction in the incidence of clinically advanced cancer, and chance, bias, and confounding cannot be ruled out with reasonable confidence. In addition, for the evaluation of effectiveness,
the balance of benefits and harms has been taken into account.

- **Inadequate evidence for the efficacy or for the effectiveness of screening by a given procedure** will apply when data on incidence or mortality are lacking, or when the number or quality of studies does not permit a conclusion.

- **Sufficient evidence that screening by a given procedure is not efficacious or effective** will apply when any of the following cases hold:
  
  o The procedure does not result in earlier diagnosis than in the absence of screening;
  
  o The survival of cases detected at screening is no better than that of cases diagnosed routinely without screening;
  
  o The screening procedure is consistently associated with no reduction in mortality from or incidence of invasive cancer, and chance, bias, and confounding can be ruled out with reasonable confidence;
  
  o There is evidence showing that harms outweigh benefits from the specific intervention.

**References**

This seventeenth Volume of the *IARC Handbooks of Cancer Prevention* series evaluates the beneficial and adverse effects of various modalities of colorectal cancer screening. It is the third Volume since the relaunch of the series in 2014.

This Volume of the *IARC Handbooks* is timely, because colorectal cancer screening has not been evaluated in previous *Handbooks*, and there are no World Health Organization recommendations for colorectal cancer screening. In addition, in 2015 the *IARC Monographs* classified processed meat as carcinogenic to humans (Group 1), on the basis of *sufficient evidence* of carcinogenicity in humans: evidence from epidemiological studies that every 50 gram portion of processed meat eaten daily increases the risk of colorectal cancer by 18% (*IARC, 2018a*).

Colorectal cancer is among the most common cancers worldwide, in both high-income countries and low- and middle-income countries. Primary prevention can be achieved by reducing exposure to preventable risk factors, such as excess body fatness (*IARC, 2018b*), consumption of alcoholic beverages (*IARC, 2012*), and tobacco smoking (*IARC, 2012*), and by increasing physical activity (*IARC, 2002*); secondary prevention provides important additional options for colorectal cancer control.

Based on a systematic review of the available literature, the Working Group made evaluations of the effectiveness of the different screening modalities reviewed. In addition, the literature was reviewed but no evaluations were made for the screening of individuals at increased risk, for strategies to increase participation in screening programmes, and for emerging techniques other than computed tomography colonography.

The aim of colorectal cancer awareness programmes is to educate individuals about the signs and symptoms of colorectal cancer and the importance of seeking early diagnosis and treatment. Overall, these steps aim to promote the early diagnosis of the disease for better treatment and prognosis and are not considered to be *screening* activities, and therefore such programmes are not included in this review.

While this Volume does not provide public health recommendations regarding implementation of colorectal cancer screening or recommendations for future research, it may serve as the scientific evidence base for implementation of national programmes.

Below are some elements discussed during the Working Group meeting that do not pertain specifically to a screening modality but may enhance the reader’s understanding of the topic under review.

**Information and awareness**

Organized screening programmes, in establishing opportunities for personal contacts with health-care providers for a large number of people, can also provide a unique opportunity...
to combine efforts for early detection of cancer with health education interventions aimed at promoting lifestyle changes among asymptomatic individuals, at a time when they may be open to learning about how to reduce cancer risk (van der Aalst et al., 2010). Unhealthy diets, physical inactivity, and smoking are key risk factors for the major noncommunicable diseases, such as cardiovascular diseases, diabetes, and cancer. The available evidence from intervention studies (Robb et al., 2010; Anderson et al., 2014) supports the hypothesis that comprehensive interventions are acceptable for asymptomatic individuals targeted for cancer screening, can favour the adoption of healthier lifestyle habits, and, according to preliminary analyses, may be cost-effective.

**Cancer prevention in low- and middle-income countries**

In most low- and middle-income countries, a uniform approach for increasing cancer control is challenging at every step of the process. Tailored preventive actions for early detection of cancer must be started concurrently with the development of a reliable health information system and, specifically, with cancer registration. In such settings, early detection strategies and access to treatment for symptomatic individuals are important components of the strategy for reducing cancer-related deaths.

**Quality assurance of organized screening programmes**

A range of screening strategies for colorectal cancer is currently available, which may show different cost–effectiveness profiles in different settings; in addition, new tests continue to emerge, based on new markers or new imaging modalities. Considering that efficient evaluation of these alternatives within the framework of screening trials presents a challenge, it has been suggested that a good health service programme should integrate the development and testing of new modalities as part of the programme itself, to be able to monitor and assess changes in clinical practice and to provide new evidence on the effectiveness of different options. Screening programmes may then represent the natural platforms for comparative effectiveness research, which could also represent an opportunity to optimize the effectiveness of screening services within existing programmes and to continuously improve their quality. Continuous and systematic monitoring of reliable and evidence-based performance indicators supports quality improvement efforts, providing comparative data as well as new evidence that may inform the adoption of screening strategies or of new tests in population programmes (Bretthauer & Hoff, 2012).

**Selection criteria for observational studies on the effects of endoscopic techniques**

In reviewing the body of evidence from observational studies of the effectiveness of endoscopic techniques in reducing colorectal cancer incidence and mortality, the Working Group determined strict criteria for inclusion of the available studies. These are the following:

- The study must have been performed in a screening setting.
- There must be a concurrent control group or groups.
- The follow-up must be of adequate length to enable an effect to be observed (> 5 years).
- The intervention must be with contemporary methods (i.e. after 1990).
• There must be a reliable end-point ascertainment.
• The study description must contain information on potential confounders (i.e. colorectal cancer risk factors, competing risks).
• The study design must not exclude prevalent cancer.

Approach for evaluating the effectiveness of emerging techniques

Currently, emerging screening technologies, such as computed tomography colonography, capsule colonoscopy, the multitarget stool DNA test, and blood DNA tests, tend to be evaluated based on performance indicators from a single screening test (typically, sensitivity and specificity), and possibly intermediate end-points associated with colorectal cancer incidence and mortality, i.e. the detection rates of cancer and of advanced adenomas.

To further evaluate the cancer-preventive effects of such technologies, high-quality observational studies could be performed to acquire evidence on cancer incidence and mortality outcomes. Also, randomized controlled trials comparing the emerging technology with one or more conventional screening methods may be undertaken to compare measures of intermediate screening outcomes and/or colorectal cancer incidence and mortality rates. However, the potential for conducting such randomized controlled trials, especially with incidence and mortality end-points, is low because of the high financial and time-related costs. The potential for randomized controlled trials is especially limited if the new technology demonstrates similar, but not substantially better, test performances when compared with conventional screening methods in a tandem study.

Even though observing a mortality reduction remains the most important initial evaluation end-point, when evidence from randomized controlled trials is lacking, once the efficacy of a screening method has been demonstrated with a randomized controlled trial it may be considered reasonable to infer that a new, similar method is efficacious if it can be consistently shown to be similarly effective in the detection of cancer and of precursor lesions (i.e. advanced neoplasia associated with colorectal cancer incidence and mortality). Typically, these intermediate end-points are measured with a prospective tandem design, in which individuals undergo testing with the new technology and then undergo testing with a similar established method as the reference standard. Although the approach has some limitations because of variable performance, performance indicators and detection rates of adenomas and of cancer are compared with those of established screening methods.

Even if the emerging technology is dissimilar to tests previously evaluated by randomized controlled trials (a stool-based test vs a blood-based test, or sigmoidoscopy vs capsule colonoscopy), it is important to carefully consider how the new test could be confidently evaluated with an observational study that compares its performance with that of a reference standard, because all screening tests for colorectal cancer aim to detect early asymptomatic disease in order to reduce cancer incidence and/or mortality. As the pace of innovation increases, these challenges will be increasingly frequent, and there is a growing literature that addresses both the need for and the suggested methodology for timely evaluation of new technologies when randomized controlled trials are not possible or practical (Meijer et al., 2009; Young et al., 2016).
Adenomatous polyps as surrogate biomarkers for primary prevention

Most colorectal cancers develop from adenomatous polyps (adenomas); therefore, people with adenomatous polyps, particularly those arising before age 60 years, are at increased risk of colorectal cancer. The malignant potential of adenomas depends largely on their histological type, grade of dysplasia, and size (Tanaka, 2009).

Removal of adenomas has been shown to reduce the risk of colorectal cancer; prevention of their development has a large potential for preventing colorectal cancer (see Section 3.3.3 for risk reduction by screening).

Recent research has been directed towards the prevention of adenomas and the use of surrogate biomarkers that are altered before polyp formation during colon carcinogenesis (Tanaka, 2009). These surrogate end-point markers could provide a simple and economical tool for preliminary assessment of potentially effective chemopreventive agents for colorectal cancer.

<td>GLOSSARY</td>
<td></td>
</tr>
<tr>
<td>---</td>
<td></td>
</tr>
<tr>
<td><strong>Adenoma detection rate</strong></td>
<td>The proportion of screening examinations (by colonoscopy or other means) in which at least one adenoma is detected.</td>
</tr>
<tr>
<td><strong>Advanced adenoma</strong></td>
<td>An adenoma with a size of more than 10 mm and/or with tubulovillous or villous architecture and/or with high-grade neoplasia.</td>
</tr>
<tr>
<td><strong>Advanced neoplasia</strong></td>
<td>Advanced neoplasia includes both advanced adenoma and invasive cancer.</td>
</tr>
<tr>
<td><strong>Background incidence rate</strong></td>
<td>The incidence rate expected in the absence of screening.</td>
</tr>
<tr>
<td><strong>Classical adenoma</strong></td>
<td>A classical colorectal adenoma is a benign, premalignant neoplasm composed of dysplastic epithelium. The descriptor “classical” distinguishes this type of adenoma from lesions in the serrated pathway.</td>
</tr>
<tr>
<td><strong>Colonoscopy</strong></td>
<td>Endoscopic examination of the proximal and distal parts of the colon (large bowel) with a charge-coupled device camera or a fibre-optic camera on a flexible tube passed through the anus.</td>
</tr>
<tr>
<td><strong>Colorectal cancer detection rate</strong></td>
<td>The proportion of screening examinations (by colonoscopy or other means) in which at least one cancerous lesion is detected.</td>
</tr>
<tr>
<td><strong>Colorectal cancer incidence rate</strong></td>
<td>The rate at which new cases of colorectal cancer occur in a population. The numerator is the number of newly diagnosed cases of colorectal cancer that occur in a defined time period. The denominator is the population at risk of a diagnosis of colorectal cancer during this defined period, sometimes expressed as person–time at risk during that period.</td>
</tr>
<tr>
<td><strong>Colorectal cancer mortality rate</strong></td>
<td>The rate at which deaths from colorectal cancer occur in a population. The numerator is the number of colorectal cancer deaths that occur in a defined time period. The denominator is the population at risk of dying from colorectal cancer during this defined period, sometimes expressed as person–time at risk during that period.</td>
</tr>
<tr>
<td><strong>Colorectal cancer register</strong></td>
<td>A record of information on all new cases of colorectal cancer and deaths from colorectal cancer that occur in a defined population.</td>
</tr>
<tr>
<td><strong>Completion rate</strong></td>
<td>The proportion of examinations completed to the desired extent: the junction of the sigmoid and the descending colon for sigmoidoscopy; the caecum for colonoscopy.</td>
</tr>
<tr>
<td><strong>Conscious sedation</strong></td>
<td>An induced state of sedation characterized by a minimally depressed consciousness such that the patient is able to continuously and independently maintain a patent airway, retain protective reflexes, and remain responsive to verbal commands and physical stimulation.</td>
</tr>
<tr>
<td><strong>Coverage by examination</strong></td>
<td>Population-based screening programmes: subjects having performed the recommended test during the reference year / number of subjects in the eligible population for the same year (total target population/screening interval). Non-population-based screening programmes/opportunistic settings: subjects up-to-date with the recommended screening protocol / target population.</td>
</tr>
<tr>
<td>Term</td>
<td>Definition</td>
</tr>
<tr>
<td>-----------------------------------------</td>
<td>-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>Deep sedation</td>
<td>An induced state of sedation characterized by depressed consciousness such that the patient is unable to continuously and independently maintain a patent airway and experiences a partial loss of protective reflexes and of the ability to respond to verbal commands or physical stimulation.</td>
</tr>
<tr>
<td>Disability-adjusted life years</td>
<td>A measure of overall disease burden, expressed as the number of years lost due to ill health, disability, or early death. This measure was developed in the 1990s as a way of comparing the overall health and life expectancy in different countries.</td>
</tr>
<tr>
<td>Distal colon</td>
<td>The last section of the colon. The distal colon includes the descending colon (the left side of the colon) and the sigmoid colon (the S-shaped section of the colon that connects to the rectum).</td>
</tr>
<tr>
<td>Effectiveness</td>
<td>A measure of the extent to which screening, when deployed in the field under real conditions, does what it is intended to do for a specified population. The most important indicator of the effectiveness of a colorectal cancer screening programme is its effect in reducing colorectal cancer mortality.</td>
</tr>
<tr>
<td>Efficacy</td>
<td>The extent to which screening produces a beneficial result under ideal conditions. Randomized controlled trials, which are conducted to initially assess whether screening works, assess efficacy by estimating a primary outcome, such as reduction in colorectal cancer mortality in the study arm compared with the control arm.</td>
</tr>
<tr>
<td>Eligible population</td>
<td>The adjusted target population, i.e. the target population minus those people who are excluded according to screening policy on the basis of eligibility criteria other than age, sex, and geographical location.</td>
</tr>
<tr>
<td>Examination coverage</td>
<td>Annual examinations as a percentage of the annual target population.</td>
</tr>
<tr>
<td>False positive</td>
<td>A test result indicating that a person has colorectal cancer when the person does not have colorectal cancer.</td>
</tr>
<tr>
<td>Faecal occult blood test (FOBT)</td>
<td>A laboratory test used to assess stool samples for hidden (occult) blood. Occult blood in the stool may indicate colon cancer or polyps in the colon or rectum.</td>
</tr>
<tr>
<td>gFOBT, high-sensitivity</td>
<td>A newer form of the guaiac faecal occult blood test, with increased sensitivity.</td>
</tr>
<tr>
<td>gFOBT, low-sensitivity</td>
<td>The first generation of the guaiac faecal occult blood test, without rehydration.</td>
</tr>
<tr>
<td>Faecal immunochemical test (FIT)</td>
<td>A faecal occult blood test based on an immunological (antigen–antibody) reaction, where the antibody binds exclusively to human haemoglobin. FIT only detects human blood from the lower intestines.</td>
</tr>
<tr>
<td>Interval cancer</td>
<td>A colorectal cancer in an individual who had a result in a screening test, with or without further assessment, that was negative for malignancy, which was diagnosed either (i) before the next invitation to screening was due or (ii) within a period equal to a screening interval for an individual who has reached the upper age limit for screening.</td>
</tr>
<tr>
<td>Interval cancer rate</td>
<td>The number of interval cancers diagnosed within a defined period since the last negative result in a screening examination, per 1000 people with negative results.</td>
</tr>
<tr>
<td>Invitation coverage</td>
<td>Annual invitations as a percentage of the annual target population.</td>
</tr>
<tr>
<td>Lead time</td>
<td>The period between when a cancer is found by screening and when it would have been detected from clinical signs and symptoms (not directly observable) in the absence of screening.</td>
</tr>
<tr>
<td>Length bias</td>
<td>The bias towards detection of cancers with longer sojourn times, and therefore a better prognosis, by screening.</td>
</tr>
<tr>
<td>Opportunistic screening</td>
<td>Screening outside an organized or population-based screening programme, as a result of, for example, a recommendation made by a health-care provider during a routine medical consultation, a consultation for an unrelated condition, on the basis of a possibly increased risk of developing colorectal cancer (family history or other known risk factor), or by self-referral of individuals. Opportunistic screening relies on individual health-care providers taking the initiative to offer screening or to encourage individuals to participate in a screening programme, or to undertake screening outside the context of any programme. Such examinations can be performed according to the public screening policies, where they exist.</td>
</tr>
<tr>
<td>Organized screening</td>
<td>Screening programmes organized at national or regional level, with an explicit policy, a team responsible for organization, invitation, and health care, and a structure for quality assurance.</td>
</tr>
<tr>
<td>Overdiagnosis</td>
<td>The diagnosis of a colorectal cancer as a result of screening that would not have been diagnosed in the patient’s lifetime if screening had not taken place.</td>
</tr>
<tr>
<td>Participation rate</td>
<td>The number of people who have a screening test as a proportion of all people who are invited to attend screening (annual examinations as a percentage of annual invitations).</td>
</tr>
<tr>
<td><strong>Polyp</strong></td>
<td>A polyp is an abnormal tissue growth that involves the most superficial (mucosal) layer of the colon wall. Endoscopically, polyps are described according to their macroscopic appearance and can be broadly divided into two types. Polyps attached to the mucosa by a stalk are designated as pedunculated, and polyps without a stalk are designated as sessile. These distinctions, along with further subtypes of sessile polyps according to the size of the peduncle, are distinguished by consensus descriptions known as the Paris classification.</td>
</tr>
<tr>
<td><strong>Positive predictive value</strong></td>
<td>The proportion of all positive results at screening that lead to a diagnosis of cancer.</td>
</tr>
<tr>
<td><strong>Prevalence</strong></td>
<td>The proportion of a population that exhibit a disease (classified as cases) at a single point in time. Approximately the product of the incidence and the average duration of the disease.</td>
</tr>
<tr>
<td><strong>Proctosigmoidoscopy</strong></td>
<td>An examination of the rectum and the lower part of the colon, using a thin, lighted instrument called a sigmoidoscope; the term “sigmoidoscopy” is preferred for convenience.</td>
</tr>
<tr>
<td><strong>Proximal colon</strong></td>
<td>The first and middle sections of the colon. The proximal colon includes the caecum (a pouch that connects the small intestine to the colon), the ascending colon (the right side of the colon), and the transverse colon (the part of the colon that goes across the body between the right and left sides of the colon).</td>
</tr>
<tr>
<td><strong>Quality-adjusted life years</strong></td>
<td>A generic measure of disease burden, including both the quality and the quantity of life lived. One quality-adjusted life year equates to one year in perfect health; if an individual’s health is below this maximum, quality-adjusted life years are accrued at a rate of less than 1 per year; being dead is associated with 0 quality-adjusted life years.</td>
</tr>
<tr>
<td><strong>Rehydration</strong></td>
<td>The process by which faecal occult blood test samples are rehydrated before analysis. When samples are rehydrated, the analytical sensitivity of the test is higher, but more false-positive results are obtained.</td>
</tr>
<tr>
<td><strong>Screening interval</strong></td>
<td>The interval between two screening episodes, within a screening programme or in an opportunistic setting.</td>
</tr>
<tr>
<td><strong>Screening policy</strong></td>
<td>A policy for a specific screening programme that defines the targeted age group and sex group, the geographical area, and other eligibility criteria; the screening test and interval; and requirements for payment or co-payment, if applicable. As a minimum, the screening protocol and repeat interval and determinants of eligibility for screening are stated.</td>
</tr>
<tr>
<td><strong>Sensitivity</strong></td>
<td>The proportion of truly diseased persons in the screened population who are identified as diseased by the screening test. The more general expression for “sensitivity of the screening programme” refers to the ratio of true positives (colorectal cancers correctly identified at the screening examination) / [true positives + false negatives] (colorectal cancers not identified at the screening examination, detected as interval cases).</td>
</tr>
<tr>
<td><strong>Serrated polyps</strong></td>
<td>Colorectal serrated lesions and polyps are characterized by a serrated (sawtooth or stellate) architecture of the epithelium.</td>
</tr>
<tr>
<td><strong>Sigmoidoscopy</strong></td>
<td>Endoscopic examination of the rectum and sigmoid colon, potentially also examining the descending colon, splenic flexure, and distal transverse colon. There are two types of sigmoidoscopy: flexible sigmoidoscopy, which uses a flexible endoscope, and rigid sigmoidoscopy, which uses a rigid device. Flexible sigmoidoscopy is the preferred and most commonly used method nowadays. In this Handbook, unless stated otherwise, the term “sigmoidoscopy” is understood to mean flexible sigmoidoscopy.</td>
</tr>
<tr>
<td><strong>Specificity</strong></td>
<td>The proportion of truly non-diseased persons in the screened population who are identified as non-diseased by the screening test (i.e. true negatives / [true negatives + false positives]).</td>
</tr>
<tr>
<td><strong>Target population</strong></td>
<td>The age-eligible population for screening, for example all people offered screening according to the policy.</td>
</tr>
</tbody>
</table>
1.1 Global burden: incidence, mortality, survival, and projections

1.1.1 Global burden

Colorectal cancer (CRC), or cancer of the large bowel, is defined here as an aggregate term covering cancers of the colon (International Statistical Classification of Diseases and Related Health Problems, 10th revision [ICD-10] code, C18), the rectosigmoid junction (ICD-10 code, C19), and the rectum (ICD-10 code, C20). Although there are exceptions, cancers of the colon usually constitute the largest subgroup and can make up two thirds of the total, with cancers of the rectosigmoid junction and the rectum making up one third.

CRC is the third most common cancer in men and the second most common cancer in women worldwide. According to the most recent estimates from GLOBOCAN (Ferlay et al., 2018a), in 2018 there were an estimated 1 006 000 new cases in men and 795 000 in women. CRC represented more than 10% of the global cancer burden; the proportions were higher only for cancers of the lung and prostate (in men) and cancer of the breast (in women). In 2018, the global age-standardized incidence rate (ASIR) for CRC was 23.1 per 100 000 in men and 15.7 per 100 000 in women. In 2018, there were an estimated 475 000 deaths from CRC in men and 387 000 in women, and the age-standardized mortality rate (ASMR) was 10.6 per 100 000 in men and 7.0 per 100 000 in women. There were an estimated 2.5 million men and 2.1 million women alive at the end of 2018 who had been diagnosed with CRC in the preceding 5 years. These 4.6 million cancer survivors represent about 12% of all 5-year cancer survivors (Ferlay et al., 2018a).

Like for most types of cancer, incidence and mortality rates of CRC increase markedly with age, and most cases and deaths occur in people older than 50 years. Of the worldwide burden of 1.80 million incident cases in 2018, 0.18 million (10%) were estimated to occur in people younger than 50 years, 1.07 million (59%) in those aged 50–74 years, and 0.55 million (31%) in those aged 75 years and older (Ferlay et al., 2018a).

1.1.2 International variation and relationship with socioeconomic development

CRC incidence rates vary substantially across the world, with the highest rates observed in Australia and New Zealand, Europe, East Asia, and North America. Incidence rates vary 10-fold in both sexes, and the estimated incidence rates are highest in Australia and New Zealand (ASIR, 40.6 and 30.5 per 100 000 in men and women, respectively) and lowest in South-Central Asia (ASIR, 5.6 and 3.5 per 100 000 in men and women, respectively) (Fig. 1.1 and Fig. 1.2). CRC mortality rates also vary across the world (although less so than those for incidence), up to 5-fold in both men and women. In both sexes, the estimated mortality rates are highest in central and eastern Europe (ASMR, 20.3 and 11.7 per 100 000 in men and women, respectively) and
**Fig. 1.1 Global distribution of estimated age-standardized (World) incidence (A) and mortality (B) rates per 100 000 for colorectal cancer in men and women, 2018**

Colorectal cancer screening

Fig. 1.2 Estimated age-standardized incidence and mortality rates per 100 000 for colorectal cancer in men and women, by large world regions, 2018

1.1.3 Survival

The regions of the world with the highest CRC incidence rates tend to have relatively low CRC mortality rates compared with parts of Africa, Asia, and South America where incidence rates are lower but, because of lower rates of survival, mortality-to-incidence ratios are considerably higher (Fig. 1.2). According to the CONCORD-3 study, the 5-year net survival for patients diagnosed in 2010–2014 was between 60% and 70% in most countries in North America and western Europe and less than 50% in several countries in Africa, Asia, eastern Europe, and South America, in some of which it was less than 40% (Allemanni et al., 2018).
1.1.4 Time trends

An analysis of CRC incidence and mortality trends over time revealed three distinct patterns by country (or population): increasing or stable incidence and mortality rates (group A), increasing incidence rates and decreasing mortality rates (group B), and decreasing incidence and mortality rates (group C) (Fig. 1.4) (Arnold et al., 2017). Group A comprised several populations in Asia, eastern Europe, and South America, whereas groups B and C comprised populations in Australia and New Zealand, Europe, Israel, Japan, North America, and Singapore. The increasing CRC mortality rates observed in group A presumably reflect increasing background incidence in populations where health service resources have not been adequate – to detect the disease at early stages and/or manage the disease once detected – to positively affect population mortality. In contrast, the decreasing CRC mortality rates observed in groups B and C are likely to represent the effects of efforts to improve early diagnosis, including through screening programmes in some countries, allied with improving treatment and management practices. The extent to which screening programmes may also act to decrease incidence rates, through detection and removal of precancerous polyps, is difficult to determine. However, this may partly explain the CRC incidence trends observed in some of the countries in group C, in some of which (e.g. Israel, Japan, and the USA) opportunistic screening has been in place for several decades. In the USA, microsimulation modelling has suggested that the decline in CRC mortality rates is consistent with a relatively large contribution from screening and a smaller but demonstrable impact of reduction in exposure to risk factors and improvements.

Year

- Incidence
- Mortality
Fig. 1.4 (continued)
in treatments (Edwards et al., 2010). Changes in exposure profiles and/or screening modalities would probably explain all of the decrease in incidence rates in countries, such as New Zealand, where organized screening has only been introduced relatively recently (and is likely to cause an initial increase in detection of prevalent cases) (Schreuders et al., 2015; Arnold et al., 2017) (see Section 2 for screening practices).

Fig. 1.5 shows time trends in CRC incidence rates by broad age groups (0–49, 50–69, and ≥ 70 years) for selected countries. Although incidence rates have been either increasing or stable over time in all three age groups in most of the countries shown, this is not the case for the USA, where rates have decreased in the two older age groups but have increased in those younger than 50 years (especially in the most recent time period). As stated above, opportunistic screening practices in the USA are likely to have contributed to the observed decreases in the older age groups. Recent increases in CRC incidence rates among people younger than 50 years have been reported in Australia, Canada, and the USA (Patel & De,
Colorectal cancer screening

These increases, which occurred after a period of declining incidence, may be due to changes in exposure to risk factors in the age group younger than 50 years (notably the increased prevalence of obesity) and/or earlier detection of existing cancers.

1.1.5 Projections of global burden

Table 1.1 shows the estimated global burden of CRC incidence and mortality in 2018 and projected to 2040, overall and by HDI category. Overall, a 71% increase in the estimated number of new cases (from 1.80 million to 3.08 million) and an 81% increase in the number of deaths (from 0.86 million to 1.56 million) are projected by 2040. Because of differential population growth levels among different HDI categories, the numbers of new cases and deaths are projected to increase more rapidly in countries with lower HDI. Although the number of new cases will remain highest in countries with very high HDI, by 2040 the number of deaths will be highest in countries with low HDI.

It is important to note that these projections take into account only global demographic changes in population structure and growth based on United Nations estimates (UNDP, 2017). The risk of developing or of dying from CRC is assumed to remain constant at 2018 levels, and no allowance is made for changes in increased detection or improvements in survival.

1.2 Classification and natural history

Several guidelines for the classification of colorectal diseases are available, as well as diagnostic criteria for relevant lesions in the population screening programmes for CRC (Quirke et al., 2011, 2012; Vieth et al., 2011; WHO Classification of Tumours Editorial Board, 2019). This section highlights the most important premalignant lesions, their risk of disease progression, and the different CRC subtypes. It also briefly touches upon the molecular background of colorectal tumours (summarized in Fig. 1.6), which is described more extensively in Müller et al. (2016), Dienstmann et al. (2017), and Rodriguez-Salas et al. (2017) (see also Section 3.8).
1.2.1 Classical adenomas

Classical adenoma is the best-known precursor of CRC. By definition, this is a lesion that contains unequivocal epithelial neoplasia. The majority of these lesions develop after a mutation occurs in the APC gene (Fearon & Vogelstein, 1990). According to the World Health Organization (WHO) guidelines (Bosman et al., 2010), three morphological types can be distinguished according to the percentage of “villousness”: tubular adenoma (< 25% villous), tubulovillous adenoma (25–75% villous), and villous adenoma (> 75% villous). These subtypes can be further divided according to the grade of neoplasia. Although initially a three-tiered system was proposed (low-, intermediate-, and high-grade neoplasia), for the sake of reproducibility, this has been discarded and a universally accepted two-tiered system (low- and high-grade neoplasia) is used. This distinction between low- and high-grade neoplasia should be made on the basis of histological criteria; architectural changes that are indicative of high-grade neoplasia (marked complex glandular crowding and irregularity of glands, cribriform architecture, and intraluminal necrosis) should be

SSL, sessile serrated lesion.
This figure indicates the molecular pathways to colorectal cancer, but there is no clear correlation with the different histological subtypes. The indicated genes are mutated either before carcinogenesis (APC in familial adenomatous polyposis and the mismatch repair genes [MMR*] in Lynch syndrome) or during carcinogenesis (in sporadic colorectal cancer); MLH1^ indicates hypermethylation.
accompanied by significant loss of cell polarity, markedly enlarged nuclei with prominent nucleoli, and dispersed chromatin pattern, often with atypical mitotic figures. The percentage of cases with high-grade neoplasia is used as a quality indicator for pathology, and it varies from less than 5% in programmes using colonoscopy to less than 10% in programmes using stool-based tests for blood (Quirke et al., 2011).

A special subcategory, advanced adenoma, has been defined for evaluation in population screening programmes. Advanced adenomas are those adenomas with a size of more than 10 mm and/or with tubulovillous or villous architecture and/or with high-grade neoplasia. Depending on national guidelines, these features may be important for the determination of the subsequent surveillance intervals.

The presence of advanced adenomas compared with non-advanced adenomas is associated with an increased risk of developing subsequent adenomas or CRC (Atkin et al., 1992; Cottet et al., 2012). Whereas the 10-year cumulative risk of developing CRC was reported to be 2.3% for patients with classical adenoma (Erichsen et al., 2016), it was estimated to be as high as 40% for elderly patients with advanced adenoma, from large-scale population studies in Germany (Brenner et al., 2007).

1.2.2 Serrated lesions and polyps

Serrated lesions and polyps are characterized by a serrated (sawtooth or stellate) architecture of the epithelium. Serrated lesions and polyps form a spectrum of lesions that have only relatively recently been found to be related to the development of CRC. As per current terminology (WHO Classification of Tumours Editorial Board, 2019), there are three types of serrated lesions and polyps: hyperplastic polyps, sessile serrated lesions, and traditional serrated adenomas.

The most common type of serrated polyp is the hyperplastic polyp. Hyperplastic polyps are often small lesions (< 5 mm in diameter) and are frequently found in the distal colon. Diminutive and distal hyperplastic polyps have no significant malignant potential and do not affect colonoscopic surveillance intervals; however, proximal microvesicular hyperplastic polyps are likely to be a precursor of sessile serrated lesions (WHO Classification of Tumours Editorial Board, 2019).

Sessile serrated lesions (“sessile serrated adenomas” and “sessile serrated polyps” are not recommended nomenclature) are considered to be precursor lesions of CRC. These lesions share with hyperplastic polyps the serrated crypt structures, but architectural distortion is also present: horizontal growth along the muscularis mucosae, dilation of the crypt base (basal third of the crypt), serrations extending into the crypt base (in contrast to superficial serrations in hyperplastic polyps), and asymmetric proliferation. Neoplasia can occur, similar to the type of neoplasia that is observed in classical adenomas (intestinal type neoplasia) or serrated neoplasia. The proportion of lesions with neoplasia can increase to more than 30% in the larger serrated lesions (Burgess et al., 2016). These lesions very often carry a BRAF mutation and often show the CpG island methylator phenotype, with promoter methylation of hMLH1, causing microsatellite instability (Bettington et al., 2017). The interobserver variation between pathologists is particularly high for these lesions (Ensari et al., 2012; Rau et al., 2014), probably because they are part of a spectrum with hyperplastic polyps. The risk of progression of a sessile serrated lesion to CRC is highest for neoplastic lesions, and the 10-year cumulative risk of developing CRC was reported to be 4.4% for patients diagnosed with a sessile serrated lesion with neoplasia (Erichsen et al., 2016).

The third type of serrated lesions and polyps, the traditional serrated adenoma, is rare and accounts for 0.5–2.5% of all colorectal polyps. The most distinctive features are the slit-like serration, tall columnar cells with intensely
eosinophilic cytoplasm and pencillate nuclei, and ectopic crypt formations along villous projections. These polyps frequently carry KRAS mutations (Bettington et al., 2015). In patients with a traditional serrated adenoma, the risk of developing advanced adenoma or CRC is more than twice that in patients with a classical adenoma, and the 10-year cumulative risk of developing CRC was reported to be 4.5% (Yoon et al., 2015; Erichsen et al., 2016).

1.2.3 Colorectal cancer

Classification of CRC is traditionally performed according to the histological subtypes as defined by WHO (WHO Classification of Tumours Editorial Board, 2019). The most common subtype is adenocarcinoma not otherwise specified, which accounts for 85% of CRC cases worldwide. The second most common subtype is mucinous carcinoma, which is characterized by the presence of mucinous lakes in at least 50% of the tumour area and accounts for 5–20% of CRC cases worldwide (Hugen et al., 2014). Previously, mucinous carcinoma had always been considered to be associated with a poor prognosis, but this no longer seems to be the case (Hugen et al., 2016). Recently, medullary carcinoma has been increasingly identified, and its frequency has been estimated to be 4% (Nagtegaal & Hugen, 2015). This subtype is characterized by solid growth in combination with an inflammatory reaction. Medullary carcinomas are almost invariably microsatellite instable, most frequently in combination with BRAF mutations (WHO Classification of Tumours Editorial Board, 2019), and the prognosis of patients with these tumours is excellent. Signet-ring cell carcinomas are relatively rare in the colon, with a reported frequency of less than 2%, and are associated with a very poor outcome (Hugen et al., 2015).

CRC can also be classified according to its location. The difference between colon cancer and rectal cancer has long been recognized, mainly because of the differences in treatment options, and recently it has garnered more interest because of the variation in possible screening modalities. However, the division of colon cancer by embryological origin (midgut or proximal colon and hindgut or distal colon) also seems relevant for outcomes, given the differences in biology and behaviour. Distal colon cancer is associated with better outcomes than proximal colon cancer, even after correction for stage (Petrelli et al., 2017).

Molecular classifications are increasingly important. Microsatellite instability is considered to be the second most common molecular pathway for the development of CRC, the first being the adenoma–carcinoma pathway involving APC mutations (see Fig. 1.6). In addition to being the result of germline mutations in Lynch syndrome, microsatellite instability is present in up to 20% of sporadic CRC as well (Li et al., 2013). The majority of tumours with microsatellite instability have hypermethylation of hMLH1, which is more commonly found in the proximal colon in elderly women (Li et al., 2013). There is an overrepresentation of mucinous carcinoma and medullary carcinoma in the group with microsatellite instability, and when restricted to early-stage disease, the prognosis of patients with these tumours is excellent.

A more complex molecular classification is that based on the findings of a large international consortium that was formed to solve the complex issue of multiple gene expression-based classifications of CRC (Guinney et al., 2015). This classification identifies five different groups: consensus molecular subtype 1 (CMS1) (microsatellite instable, immune activation), CMS2 (canonical), CMS3 (metabolic), CMS4 (mesenchymal), and a mixed group that cannot be further classified.
1.3 Stage at diagnosis, survival, and treatment

1.3.1 Stage at diagnosis

The staging system used for CRC is the tumour–node–metastasis (TNM) classification, which is based on the original publication by Dukes (Dukes, 1932). The T refers to the extent of invasion depth of the tumour in the various layers of the bowel wall (T1, submucosa; T2, muscularis propria; T3, mesocolic or mesorectal fat; and T4, perforation of serosa or ingrowth in other organs). The N refers to the number of lymph nodes involved (N0, no involved lymph nodes; N1, 1–3 nodes involved; and N2, 4 or more nodes involved) (Sobin, et al., 2009). Recently, a special nodal category, N1c, was created to indicate the presence of tumour deposits in the absence of lymph node metastases; this has been subject to much debate in the literature (Nagtegaal et al., 2012, 2017), which complicates treatment choices. The M refers to the presence of distant metastasis (M0, no distant metastasis; M1, metastasis beyond regional lymph nodes).

The T, N, and M stages are combined into the stage classification. The stages for CRC are as follows: stage I is early-stage cancer that is limited to the bowel wall (T1, T2) and without lymph node metastases; stage II is cancer without lymph node metastases and T3–T4 tumours; stage III is cancer without distant metastases but with lymph node metastases; and stage IV is cancer with distant metastases (M1) at diagnosis. The T, N, and M stages are not independent. With increasing T stage, the risk of lymph node metastases and distant metastases increases, and with increasing N stage, the risk of distant metastases also increases. Tis, which refers to carcinoma in situ, is not considered to be cancer but should be regarded as high-grade neoplasia (Bosman et al., 2010).

Stage at diagnosis is influenced by multiple factors and varies widely. Because not all cancer registries routinely report these data, few large-scale studies are available. Also, several studies have reported using a three-tiered system, consisting of localized disease (TNM stages I and II), regional spread (TNM stage III), and distant spread (TNM stage IV). It is difficult to compare studies from different periods and locations, because many factors may be responsible for the reported differences, including treatment strategies, age distribution of the population, access to health care, diagnostic options, and the quality of the registration and the diagnostic workup. Improved diagnostic possibilities may increase the number of stage IV cancers, because as the resolution of imaging techniques increases, a greater number of and smaller distant metastases may be detected. Table 1.2 summarizes stage distribution at diagnosis in population data that were collected predominantly before the full implementation of organized population screening programmes. Early detection of cancer, as a result of population screening programmes, opportunistic screening, increased awareness, and surveillance programmes for high-risk patients, may result in lower stages at diagnosis. Indeed, pilot studies, trials, and population-based investigations have shown an increase in the number of early-stage cancers, with a concomitant decrease in the number of stage IV cancers (Lindebjerg et al., 2014; Yang et al., 2014; Binefa et al., 2016; Kubisch et al., 2016).

1.3.2 Survival

The relationship between stage and outcome is evident: the higher the tumour stage, the shorter the survival time. Although almost all individual studies show this effect, there is a relative shortage in the literature on the comparison of stage-dependent outcomes in larger cohorts worldwide (Table 1.3 and Table 1.4). A recent study comparing outcomes in six high-income countries showed evident differences, with the

<sup>a</sup> Only populations between age 50 years and age 79 years are included.
1.3.3 Treatment

Treatment advice is dependent on the stage of disease. The decision about whether to administer neoadjuvant treatment is based on the stage determined by imaging. In particular, an advanced T stage in rectal cancer is an indication for neoadjuvant radio(chemo)therapy. Other treatment decisions are based on pathological staging. For early pT1 cancers, the risk of lymph node metastases is low and local treatment may therefore be sufficient. For a more balanced risk evaluation in those patients, additional histological biomarkers are usually included in the discussion (Bosch et al., 2013). When only tumour stage is taken into consideration, adjuvant chemotherapy is usually advised for patients with stage III disease, as well as for high-risk patients with stage II disease (Benson et al., 2004). For patients with stage IV disease, a personalized approach is chosen, which varies between the resection of limited metastatic disease and palliative systemic therapy and combinations thereof. In general, treatment decisions are made at multidisciplinary team meetings.

1.4 Risk factors and protective factors

Unlike for some other cancers, such as those of the lung or the skin, there is no single risk factor that accounts for most cases of CRC. Factors associated with high relative risks, such as inherited conditions, are uncommon and are

lowest stage-corrected survival in the United Kingdom (Maringe et al., 2013).

SEER, Surveillance, Epidemiology, and End Results.
often non-modifiable, so that most of the disease burden at the population level is attributable to factors associated with lower relative risks, many of which are potentially modifiable.

Here, risk factors and protective factors are broadly grouped into three types: lifestyle and environmental factors, host factors, and use of medications. The relative magnitudes of the effects associated with these risk factors and protective factors, based on the most recent systematic reviews and meta-analyses, are presented in Table 1.5 and Table 1.6, respectively. Factors associated with a high predisposition to CRC, which usually require close medical surveillance of the people with such risk factors outside population screening, are addressed in Section 3.8.

### 1.4.1 Lifestyle and environmental factors

#### (a) Diet

Food and nutrition play an important role in the prevention and the causation of CRC. Established risk factors are presented in Table 1.5.

There is sufficient evidence that consumption of processed meat increases the risk of CRC (WCRF/AICR, 2017; IARC, 2018a), with strong evidence of the mechanisms operating in humans (IARC, 2018a). [The differences in the assessment of processed meat consumption across studies included in meta-analyses should be kept in mind.] Consumption of alcoholic beverages increases the risk of CRC, with a monotonic dose-dependent relationship above 30 g/day (about two drinks per day) (IARC, 2012; Scoccianti et al., 2015; WCRF/AICR, 2017); the risk is greater in men than in women, and is similar for wine, beer, and spirits. The mechanisms of carcinogenesis operating in humans have been well established (IARC, 2012).
Consumption of red meat probably increases the risk of colorectal cancer (WCRF/AICR, 2017; IARC, 2018a). In addition, there is suggestive evidence that consuming foods containing haem iron increases the risk of CRC (WCRF/AICR, 2017).

Consuming foods containing dietary fibre, especially whole grains, probably decreases the risk of CRC, with dose–response relationships (Table 1.6) (Aune et al., 2011; Norat et al., 2015; WCRF/AICR, 2017). The protective effect appears to be more robust for fibre from grains than for other sources of fibre (i.e. fruits and vegetables) (IARC, 2003). Consumption of dairy products (total dairy, milk, cheese, and dietary or supplemented calcium intakes) is also probably protective against CRC, with a clear dose–response relationship (WCRF/AICR, 2017). The effect is likely to be mediated by calcium (Keum et al., 2014), for which evidence of a protective effect is probable (WCRF/AICR, 2017). [Most of the evidence comes from high-income countries, where dietary calcium intake can be used as a marker for dairy consumption.] Calcium intake also decreases the risk of adenomas, particularly advanced adenomas, over a wide range of calcium intake, with a clear dose–response relationship (Keum et al., 2015). Evidence for a protective effect of eating non-starchy vegetables and fruits, fish, foods containing vitamin C, and foods containing vitamin D, and of taking multivitamin supplements is suggestive, based on reasonably consistent but still limited data (WCRF/AICR, 2017).

(b) Body fatness and abdominal fatness

There is sufficient evidence of an increased risk of CRC with increasing body fatness and abdominal fatness, with clear dose–response relationships and strong mechanistic data (Anderson et al., 2015; Lauby-Secretan et al., 2016; WCRF/AICR, 2017; IARC, 2018b). The effect is greater for colon cancer than for rectal cancer and, for body fatness only, is larger for men than for women (Harriss et al., 2009; WCRF/AICR, 2017). Although an unhealthy weight is often considered to be a result of potentially modifiable individual choices, it is now recognized that an obesogenic environment (i.e. sociocultural, economic, and marketing influences) poses challenges to the

* A protective effect has been found for colon cancer (RR, 0.80; 95% CI, 0.72–0.88) but not for rectal cancer (RR, 1.04; 95% CI, 0.92–1.18).
achievement of a healthy lifestyle (Kopelman, 2007; Mackenbach et al., 2014).

(c) Physical activity

Physical activity reduces the risk of colon cancer (IARC, 2002; WCRF/AICR, 2017). The protective effect appears to be slightly greater for recreational activity than for occupational physical activity (Mahmood et al., 2017). Two recent meta-analyses estimated similar decreases in risk of proximal and distal colon cancers among the most physically active compared with the least active individuals (Boyle et al., 2012; Robsahm et al., 2013). In contrast, physical activity appears to be unrelated to the risk of rectal cancer (Robsahm et al., 2013; WCRF/AICR, 2017). Cohort studies have shown that the beneficial effect of physical activity is independent of BMI (Leitzmann et al., 2015). Overall, there is a dose–response relationship with risk reduction across a wide range of the frequency and intensity of physical activity, and exercise does not need to be intense or long-lasting to have substantial benefits.

(d) Tobacco smoking

There is sufficient evidence that tobacco smoking causes CRC, with comparable increases in risk in current and former smokers (IARC, 2012). Dose–response studies also clearly demonstrate that the risk of CRC increases with increasing intensity and duration of smoking. The risk is consistently higher for rectal cancer than for colon cancer (Liang et al., 2009).

1.4.2 Host factors

(a) Attained height

There is convincing evidence that genetic, environmental, hormonal, and nutritional factors that lead to greater linear growth and greater attained adult height cause CRC, with a clear dose–response relationship (WCRF/AICR, 2017). The association between adult attained height and risk of CRC is stronger for women than for men and is stronger for colon cancer than for rectal cancer. Nutrition during early life, hormone profiles, and sexual maturation are likely to be relevant.

(b) Sex

There is a 1.47 male-to-female ratio of incidence rates for CRC worldwide, and the excess risk for men is observed in almost all regions (Ferlay et al., 2018a). The male–female disparity in the age-related risk of CRC is probably due to sex differences in the exposure to (and, to a lesser extent, in the effects of) risk factors such as lifestyle, diet, smoking, and obesity. Interactions between estrogen exposure, body fat distribution, and the biological underpinnings of colorectal tumours also may explain this sex-related difference as well as the higher proportion of proximal colon cancers in women than in men (Chacko et al., 2015).

(c) Age

In many populations, the incidence rates of CRC are relatively low in people younger than 50 years (accounting for ~10% of cases) but increase strongly with age (Ferlay et al., 2018a) (see also Section 1.1). Worldwide, the risk of developing CRC increases by a factor of about 1.5 between each successive 5-year age group in the age range 45–74 years, with some variations across populations (Ferlay et al., 2018a).

(d) Ethnicity

The factors underlying the substantial ethnic and racial disparities in the risk of and subsite distribution of CRC are multiple and complex, and these disparities are only partly attributable to differences in the prevalence of exposure to risk factors (Ollberding et al., 2011). Differences in genetic susceptibility and gene–environment interactions contribute to explain the disproportionately high risk of CRC worldwide in
Ashkenazi Jews (lifetime risk up to 15%) (Locker & Lynch, 2004) and the higher risk in Black and Asian people compared with White and Latino people (Ollberding et al., 2011). Compared with White people, Black people are more likely to have CRC diagnosed at an advanced stage and to have proximal CRC (Ollberding et al., 2011).

1.4.3 Use of medications

(a) Aspirin and other non-steroidal anti-inflammatory drugs

The evidence from follow-up of randomized trials (after about 20 years) and from observational studies demonstrates that long-term, low-dose, and regular use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs) effectively reduces the risk of CRC in average-risk individuals (Rothwell et al., 2010; Huang et al., 2015). The dose–risk and duration–risk relationships between regular use of aspirin and CRC risk show that even low-dose (≤ 75 mg/day) and low-frequency (twice a week) intake of aspirin has a benefit, with a levelling off for a frequency of more than 7 times per week (Ye et al., 2013). However, the greater risks of developing ulcers, serious ulcer complications, and cardiovascular events associated with regular use of aspirin limit its potential for chemoprevention of CRC.

(b) Hormone replacement therapy

Results from meta-analyses consistently show that the use of hormone replacement therapy (HRT) is associated with a reduced risk of CRC (Friis et al., 2015). The reduction in risk is larger among current users of HRT than among former users, and, to a lesser degree, with increasing duration of use (Green et al., 2012; Johnson et al., 2013). Questions remain about how long the preventive benefits of HRT persist after use is discontinued. Although the use of HRT has benefit in reducing the risk of developing CRC, the potential harms, including increased risks of cardiovascular disease and gynaecological cancers, make the use of HRT unsuitable for primary prevention in women in the general population (Friis et al., 2015).

(c) Other medications

Randomized controlled trials (RCTs) showed a substantial reduction in the risk of developing colorectal adenomas and advanced adenomas over a 3-year follow-up period with use of cyclooxygenase-2 (COX-2) inhibitors (Rostom et al., 2007). Like NSAIDs, these chemopreventive agents are associated with increased risks of adverse cardiovascular outcomes and gastrointestinal harms.

A meta-analysis of five observational studies indicated a protective effect of metformin treatment against CRC in patients with type 2 diabetes (Zhang et al., 2011), and in one short-term RCT using aberrant crypt foci as endoscopic surrogate markers, a protective effect has also been suggested in people without diabetes (Hosono et al., 2010). The common side-effects of metformin include diarrhoea, nausea, and abdominal pain.

(d) Dietary supplements

In a meta-analysis of 20 prospective observational studies, dietary or supplemented calcium intake has been shown to reduce the risk of CRC, with a linear dose–response relationship (Keum et al., 2014). However, RCTs have not shown a consistent protective effect against CRC (Keum et al., 2017; WCRF/AICR, 2017). To date, RCTs of other dietary supplement interventions have not demonstrated a protective effect (Norat et al., 2015). Studies with folic acid (folate), beta-carotene, selenium, and vitamin D supplementation yielded null findings, sometimes with an unexpected increased risk of other types of cancer. Use of dietary supplements for CRC chemoprevention is not currently recommended.
1.4.4 Etiological differences by subsite

Some etiological and biological differences exist between CRC subsites (Lee et al., 2017). Risk factors such as BMI and height are more important for colon cancer than for rectal cancer, whereas tobacco smoking may influence the risk of rectal cancer more than that of colon cancer (WCRF/AICR, 2017). Physical activity appears to influence the risk of colon cancer but not that of rectal cancer. Differences in embryological sources and physiological functions, affecting bile-acid metabolism, faecal composition, and transit time, have been advanced to explain these etiological differences between subsites. Neither differences related to subsite nor sex-related differences in the magnitude of risk are considered in Table 1.5 and Table 1.6.

2. AVAILABILITY AND USE OF COLORECTAL CANCER SCREENING

2.1 Europe

In this section, the following 47 countries are considered: the 28 Member States of the European Union (EU) and Albania, Andorra, Armenia, Azerbaijan, Belarus, Bosnia and Herzegovina, Georgia, Iceland, Liechtenstein, Monaco, Montenegro, Norway, the Republic of Moldova, the Russian Federation, San Marino, Serbia, Switzerland, the former Yugoslav Republic of Macedonia, and Ukraine.

During the past decade, since the publication of the first EU report on cancer screening activity (Von Karsa et al., 2008), a substantial improvement has taken place in the implementation of colorectal cancer (CRC) screening in Europe. Information about CRC screening policies, strategies adopted in current programmes, implementation status, and participation in screening activities is available from five recent surveys. One of them focused on the EU Member States (Altobelli et al., 2014), two reported information from non-EU countries in Europe (Altobelli et al., 2016; Giordano et al., 2016), and the other two reported European data as part of a worldwide survey of CRC screening (Benson et al., 2008; Schreuders et al., 2015). Additional data are available from the second EU report on cancer screening (Ponti et al., 2017), which reported updated information about policies, strategies, and organization of screening in EU Member States, as well as quantitative performance data for breast cancer, cervical cancer, and CRC screening programmes.

The involvement of experts and stakeholders from several EU Member States in the development of EU guidelines (Segnan et al., 2010), together with the implementation of international cooperative projects – the European Partnership for Action Against Cancer (EPAAC) (European Partnership for Action Against Cancer, 2012), Europe against Cancer: Optimisation of the Use of Registries for Scientific Excellence in Research (EUROCOURSE) (Anttila et al., 2015), and the Joint Action on Cancer Control (CANCON) programmes (Albreht et al., 2017) – extended to new EU Member States from eastern and central Europe, contributed to the adoption of a common framework for the implementation of population-based programmes, reaching a large proportion of the European population.

More recently, cooperation has also been extended to European countries that are not members of the EU, within the framework of the EUROMED CANCER Network project (Giordano et al., 2016), which supports the development of the skills, organizational resources, and infrastructure that are needed to implement high-quality screening.
2.1.1 Guidelines

In 2003, the EU Council called for the introduction of evidence-based screening, adopting a population-based approach (European Council, 2003). Only the guaiac faecal occult blood test (gFOBT) was recommended as the primary screening test for people aged 50–74 years.

More recently, the EU quality assurance guidelines for CRC screening, developed following an evidence-based methodology (Segnan et al., 2010), concluded that there was good evidence to support the adoption of gFOBT, reasonable evidence of the effectiveness of the faecal immunochemical test (FIT), reasonable evidence (only one trial had been published at the time) of the effectiveness of sigmoidoscopy, and limited evidence of the effectiveness of primary screening with colonoscopy. No evidence was available on the effectiveness of newer tests (computed tomography [CT] colonography, capsule colonoscopy, or stool DNA tests), which were not recommended for screening average-risk subjects. FIT was recommended as the faecal test of choice for population-based programmes.

2.1.2 Policies

To maximize the impact of screening, the EU guidelines (Segnan et al., 2010) recommended the implementation of organized programmes, which, unlike opportunistic screening or case finding, can ensure high coverage and equity of access and enable comprehensive quality assurance. By 2016, population-based organized programmes had been established or piloted in 22 of the 28 EU Member States (Table 2.1), and Germany is planning to switch from the current opportunistic screening to a population-based programme in 2019. Non-population-based programmes exist in Greece and Latvia (Ponti et al., 2017).

Seven of the 19 non-EU countries in Europe (Georgia, Monaco, Montenegro, Norway, San Marino, Serbia, and Switzerland) have adopted at least some policies to implement or pilot population-based programmes (Table 2.1). Among Balkan countries outside the EU, population-based programmes exist in Montenegro and in Serbia, and opportunistic screening is available in Bosnia and Herzegovina, whereas no programmes have been implemented in Albania or the former Yugoslav Republic of Macedonia (Schreuders et al., 2015; Altabelli et al., 2016; Giordano et al., 2016; Scepanovic et al., 2017). In Switzerland, the canton of Vaud has launched a systematic organized CRC screening programme, offering both FIT and colonoscopy to the eligible population (Selby et al., 2016). In Iceland, the implementation of a population-based programme offering biennial screening with FIT, which had been planned for 2008, was postponed because of the onset of the economic crisis (Altabelli et al., 2016). Pilot projects comparing FIT and sigmoidoscopy are under way in Norway (Bretthauer & Hoff, 2012). No programmes have been implemented in Andorra or Liechtenstein (Schreuders et al., 2015; Altabelli et al., 2016).

In the Russian Federation, CRC screening is not included in the National Priority Project “Health”, which provides guidelines for cancer prevention efforts (Avksentyeva, 2010; Goss et al., 2014). Among the other European countries of the former Soviet Union, only Georgia has recently implemented a pilot project with gFOBT (Altabelli et al., 2016). Belarus has implemented a project to assess the performance of FIT among asymptomatic subjects who undergo colonoscopy at a single institution, to obtain information useful for planning the implementation of national screening (Rebeko et al., 2016). In Ukraine, CRC prevention was included in the most recent cancer plan, for 2002–2006, but no information is available about the current implementation (Altabelli et al., 2016). No programmes have been implemented in the remaining countries (Altabelli et al., 2016; Giordano et al., 2016).

FIT, faecal immunochemical test; FS, flexible sigmoidoscopy; gFOBT, guaiac faecal occult blood test; NA, not applicable; NR, not reported; TC, total colonoscopy.

- Only countries that have implemented a population-based programme or have introduced some recommendations or policies for opportunistic (non-population-based) screening are included. No official recommendation or screening policy was available for the following countries: Albania, Andorra, Armenia, Azerbaijan, Belarus, Bulgaria, Iceland, Liechtenstein, the Republic of Moldova, Romania, the Russian Federation, Slovakia, the former Yugoslav Republic of Macedonia, and Ukraine.
- Examination coverage: the number of people screened with the recommended test in a given year divided by the number of people eligible for screening (the eligible target population per screening interval) in the same reference year.
- Invitation coverage: the number of people invited to screening in a given year divided by the number of people eligible for screening (the eligible target population per screening interval) in the same reference year.
- Participation rate (only for population-based organized programmes): the number of people screened divided by the eligible number of people invited to screening during the reference period.

- In Austria, a population-based screening programme is implemented in Burgenland only; opportunistic screening is available in the rest of the country.
- In the Czech Republic, opportunistic screening has been under way since 2000; since 2014, invitations have been sent only to non-attenders.
- In Germany, a population-based programme is expected to start in 2019; examination coverage represents the estimated 10-year cumulative participation rate in a colonoscopy programme among subjects aged 55–74 years (Altenhofen, 2016).

- In Italy, screening started in 1982 in Florence, and between 2000 and 2004 in other regions; in Piedmont, subjects are invited to undergo FS, and FS refusers are offered biennial FIT.
- In Lithuania, the population-based programme started in 2009 in two districts and became nationwide in 2014.
- In Sweden, only the Stockholm-Gotland region has introduced screening.
- In Switzerland, a screening programme has been implemented in the canton of Vaud; only opportunistic screening is available in the rest of the country (Selby et al., 2016).
- Year of programme initiation: 2006 (England), 2010 (Northern Ireland), 2007 (Scotland), and 2008 (Wales).
Population-based programmes are publicly funded and the screening tests are provided free of charge, except in Croatia, where the costs are reimbursed through the health insurance system (Ponti et al., 2017), and in Switzerland, where individuals are required to make a 10% co-payment for all costs (Auer et al., 2015). In the non-population-based programmes in Austria, Germany, Greece, and Latvia, the cost of the tests is covered by the health system or by health insurance (Ponti et al., 2017).

2.1.3 Programme implementation

(a) Organization

Call–recall systems, which ensure active invitation of the entire target population at regular intervals by sending written invitation letters to all eligible subjects identified through screening registries, have been implemented in all population-based programmes in the EU, except in Lithuania, where invitations are sent through primary health care providers (Ponti et al., 2017). In non-EU countries in Europe, subjects in the target age range are often invited by general practitioners or by other primary health care providers (Giordano et al., 2016). In Switzerland (canton of Vaud), a decision aid is mailed to citizens in the target age range that conveys information about the programme and the available screening modalities and encourages discussion with the individual’s primary care physician, who will propose one of the available tests (Selby et al., 2016).

(b) Target age range

The 2003 EU Council recommendation (European Council, 2003) indicated that screening should be offered to all subjects aged 50–74 years, and left the option of adopting a narrower age band, based on national prioritization. The European Code Against Cancer (Armaroli et al., 2015) recommended to start inviting people aged 50–60 years and to continue sending invitations up to ages 70–75 years. The expected cost–effectiveness ratio of different policies depends on several factors, including background risk, target age range, screening method, organization of the programme, and availability of health-care resources. Issues related to colonoscopy capacity influence the choice of both the method and the target age range. About half of the population-based programmes (Table 2.1) start screening at age 55 years or age 60 years and stop screening at age 69 years (Ponti et al., 2017). A stopping age for screening is often not defined by non-population-based programmes, which often also target subjects outside the age range for which a favourable balance of benefits and harms has been demonstrated.

(c) Screening strategy

Most EU Member States have adopted FIT as the CRC screening method or are in the process of switching from gFOBT to FIT (Ponti et al., 2017) (Table 2.1); gFOBT is still offered in Croatia, Finland, and the United Kingdom as well as in the non-population-based programmes in Greece and Latvia (Ponti et al., 2017). FIT has been adopted in the non-EU countries in Europe that have started population-based programmes, except in the pilot programme in Georgia, which offers gFOBT (Altobelli et al., 2016; Giordano et al., 2016) (Table 2.1). Only Poland has implemented colonoscopy screening within a pilot organized programme, with active invitation of the target population. Colonoscopy is recommended within the opportunistic screening in Austria, Germany, and Greece, although a pilot population-based programme with FIT is under way in one region (Burgenland) in Austria. The population-based programmes in the Czech Republic (Ponti et al., 2017), Luxembourg (Ponti et al., 2017), and Switzerland (canton of Vaud) (Selby et al., 2016) offer the option to choose between colonoscopy and FIT. Primary screening with sigmoidoscopy has been implemented in England and in one region (Piedmont) in Italy;
in both programmes, FIT is also offered, either as an alternative test for those who decline sigmoidoscopy or as an additional test for subjects older than 60 years (Ponti et al., 2017).

The screening interval for stool-based tests for blood is 2 years in most population-based and non-population-based programmes. A 1-year interval has been adopted in the population-based programmes with FIT in Austria (Burgenland) and the Czech Republic (for subjects aged 50–54 years) and in the non-population-based programmes in Germany (offering FIT to subjects aged 50–54 years) and Latvia (offering gFOBT to subjects aged 50–74 years). Colonoscopy is offered at a 10-year interval in non-population-based programmes or in programmes that offer a choice between FIT and colonoscopy (Selby et al. 2016; Ponti et al., 2017), whereas both colonoscopy and sigmoidoscopy are offered once in a lifetime in organized programmes that use endoscopy as the primary screening test.

(d) Quality assurance

The EU guidelines (Segnan et al., 2010) provide guiding principles and evidence-based recommendations on the quality assurance that should be followed when implementing CRC screening programmes. The guidelines also outline key performance indicators and standards that cover the different phases of the process, including organization, primary screening, diagnostic assessment, treatment, and surveillance. Quality assurance initiatives that focus more specifically on the laboratory standards for FIT (Fraser et al., 2012) and on endoscopy services (Sint Nicolaas et al., 2012; Joint Advisory Group on Gastrointestinal Endoscopy, 2013) have also been implemented, facilitating national and international comparisons and benchmarking.

Organized screening programmes are incorporating comparative effectiveness research projects: the programmes in Finland and Poland have been implemented with a randomized design that enables the impact of the adopted strategy to be assessed (Malila et al., 2005, 2008; Kaminski et al., 2015), and randomized comparisons of different screening strategies have been conducted, or are under way, within established programmes in France (Fairev et al., 2012), Italy (Segnan et al., 2005, 2007; Grazzini et al., 2009; Giorgi Rossi et al., 2011), the Netherlands (van Rossum et al., 2009; Hol et al., 2010; Stoop et al., 2012), Norway (Brethauer & Hoff, 2012), Sweden (Aronsson et al., 2017) and the United Kingdom (Digby et al., 2013; Moss et al., 2017).

2.1.4 Participation

Participation rates in population-based organized CRC screening programmes vary widely across countries (Ponti et al., 2017). The screening strategy influences the participation rate; there is a general trend towards a higher participation rate among subjects invited to FIT screening than among those invited to gFOBT screening. Compared with men, women consistently show a higher participation rate in gFOBT or FIT programmes and a lower response to invitations for endoscopy screening. Overall, endoscopy screening programmes show a lower participation rate compared with gFOBT or FIT programmes.

[It should be taken into account that the available data are based on the comparison of the participation rate in a single invitation round, whereas the appropriate (and relevant) comparison should balance the proportion of regular participants over several rounds of screening with gFOBT or FIT and the proportion of attendees in a single endoscopy screening during the same interval.]
2.2 Canada and the USA

Screening for CRC was pioneered in the USA and is well established in both Canada and the USA. This is due to the high incidence of CRC in these countries and the evidence produced by the National Polyp Study (Winawer et al., 1993) and by randomized controlled trials with gFOBT conducted in the USA in the past decades. In Canada, CRC screening is offered through population-based programmes, whereas in the USA, CRC screening is mainly opportunistic (Table 2.2).

2.2.1 Canada

In 2008, Canada established an organized CRC screening programme, by province. The Canadian Task Force on Preventive Health Care recommends screening average-risk adults aged 50–74 years with gFOBT or FIT every 2 years or with sigmoidoscopy every 10 years (Canadian Task Force on Preventive Health Care, 2016). Colonoscopy is not recommended as a primary screening test for CRC; in some provinces, it is recommended only for those with a family history of CRC in one or more first-degree relatives.

All 10 Canadian provinces have announced, planned, or implemented organized CRC screening programmes (Canadian Partnership Against Cancer, 2017), whereas the three territories of Canada do not have organized CRC screening programmes. Implementation of a screening programme is particularly challenging in the territories, because of a lack of resources and facilities. Also, the very low population density across a vast territory means that CRC screening is not cost-effective.

Ontario’s ColonCancerCheck, the first organized CRC screening programme in Canada, launched CRC screening throughout the province in 2008 (Rabeneck et al., 2014). In 2010–2011, the participation rate in gFOBT screening was 29.8%. In 2013, 58% of the target population had participated in CRC screening, taking into account all screening modalities. Early aggregate results from the first round of screening (from January 2009 to December 2011) of five other provincial programmes (in British Columbia, Manitoba, Nova Scotia, Prince Edward Island, and Saskatchewan) showed a much lower participation rate (16.1%) (Major et al., 2013). In 2013–2014, participation rates ranged from 8.6% to 53% across the provinces, all below the target rate (≥ 60%) (Canadian Partnership Against Cancer, 2017). The retention rate, which is defined as the percentage of individuals rescreened within 30 months after a normal result from a stool-based test for blood, ranged from 38.9% to 77.4%.

The 2012 Canadian Community Health Survey reported that more than half of Canadians were up to date with CRC screening in 2012, but there were large differences among provinces (Singh et al., 2015). In 2012, the prevalence of up-to-date CRC screening among people aged 50–74 years was 55.2%, ranging from 41.3% in the territories to 67.2% in Manitoba; the average prevalence of sigmoidoscopy or colonoscopy screening was 37.2% (highest in Ontario, at 43.3%) and of gFOBT screening was 30.1% (highest in Manitoba, at 51.7%). About 41% of those who had been screened with gFOBT had also been screened with sigmoidoscopy or colonoscopy. Individuals in the groups with the highest education level or income were more likely to comply with the CRC screening programme compared with those in groups with lower education level or income.

The National Colorectal Cancer Screening Network regularly collects data on national quality indicators for organized screening programmes, to track programme progress and identify opportunities to maximize the quality and benefit of CRC screening for all eligible Canadians (Canadian Partnership Against Cancer, 2017). The Canada-Global Rating Scale is an online survey to monitor the quality of

CTC, computed tomography colonography; FIT, faecal immunochemical test; FS, flexible sigmoidoscopy; gFOBT, guaiac faecal occult blood test; mt-sDNA, multitarget stool DNA; TC, total colonoscopy.

- Examination coverage: the number of people screened with the recommended test in a given year divided by the number of people eligible for screening (the eligible target population per screening interval) in the same reference year.
- FS is used only in one province.
- According to the 2015 National Health Interview Survey; endoscopy includes FS in the past 5 years or TC in the past 10 years, stool-based test for blood includes gFOBT or FIT in the past year, and combined includes either endoscopy or stool-based test for blood ([ACS, 2017](#)).
endoscopy services. It consists of two parts: clinical quality (consent process including patient information, safety, comfort, quality of the procedure, appropriateness, and communicating results) and quality of the patient experience (equality of access, timeliness, booking choice, privacy and dignity, aftercare, and ability to provide feedback) (Canadian Partnership Against Cancer, 2016).

2.2.2 USA

The United States Preventive Services Task Force (USPSTF) recommends CRC screening in the USA starting at age 50 years and continuing until age 75 years (U.S. Preventive Services Task Force, 2017). The recommendations of the USPSTF also indicate that the decision about whether to screen for CRC in adults aged 75–85 years should be an individual one, taking into account the patient’s overall health and prior screening history. Screening would be appropriate among adults who (i) are healthy enough to undergo treatment if CRC is detected and (ii) do not have comorbid conditions that would significantly limit their life expectancy (U.S. Preventive Services Task Force, 2017).

Screening strategies recommended by the USPSTF include any one of the following options: (i) annual screening with FIT, (ii) screening every 10 years with sigmoidoscopy and annual screening with FIT, (iii) screening every 10 years with colonoscopy, and (iv) screening every 5 years with CT colonography. The USPSTF also stated that screening with the multitarget stool DNA (mt-sDNA) test every 3 years would provide about the same amount of benefit as screening with sigmoidoscopy alone every 5 years (U.S. Preventive Services Task Force, 2017).

The USPSTF recognized that clinical decisions involve more considerations than evidence alone. Clinicians should not only understand the evidence but also individualize decision-making to the specific patient or situation. Similarly, the USPSTF noted that decisions about policy and coverage involve considerations in addition to the evidence of clinical benefits and harms.

In the USA, participation in CRC screening has been reported to have risen steadily from about 35% in the 1980s to more than 65% in 2010 (Doubeni, 2014). Among different ethnic groups in the country, participation is highest in Whites, followed by African Americans, and is lowest in Hispanics.

Data from the annual Behavioral Risk Factor Surveillance System survey revealed that in 2012, approximately 65% of adults in the USA were up to date with CRC screening, and colonoscopy was the most widely used technique (Centers for Disease Control and Prevention, 2013). The proportion of adults who had never been screened was higher in those without health insurance (55%) than in those with health insurance (24%) and higher in those without a regular health care provider (61%) than in those with a regular health care provider (24%) (Centers for Disease Control and Prevention, 2013).

The National Health Interview Survey reported that in 2015, almost 63% of adults in the USA aged 50 years and older were up to date with CRC screening, in accordance with guidelines; 60.3% of subjects had been screened by endoscopy (sigmoidoscopy in the past 5 years or colonoscopy in the past 10 years), and 7.2% had been screened with a stool-based test for blood (gFOBT or FIT in the past year) (ACS, 2017).

The National Colorectal Cancer Roundtable launched the “80% by 2018” initiative to increase participation in CRC screening (NCCRT, 2017). A recent study investigated the adherence of the population aged 50–54 years to the USPSTF CRC screening recommendations, using a large, continuously insured screening population during a 10-year period (Cyhaniuk & Coombes, 2016). The report showed that 64% of that population were adherent to the current USPSTF CRC screening recommendations; 12% were
considered inadequately screened, and 24% had never participated in CRC screening. In those subjects who received CRC screening in whichever form, the average age at screening initiation was 53 years. Of those subjects who were inadequately screened, nearly half (46%) received only one test (gFOBT or FIT) over the 10-year period.

Quality initiatives supported by national organizations and gastrointestinal societies such as the USPSTF, the American Cancer Society, the American Gastroenterological Association, the American Society for Gastrointestinal Endoscopy, and the National Colorectal Cancer Roundtable, among others, have played a significant role in increasing participation in screening in the USA.

Some organized screening programmes have also been established in the USA. Two prime examples are the Kaiser Permanente Northern California organized screening programme and the Veterans Health Administration programme. Participation rates in the Kaiser Permanente Northern California programme have doubled since 2004, to almost 80% in 2013 (Mehta et al., 2016); participation rates in the Veterans Health Administration programme among veterans 52 years or older were 68% in 2001 (Chao et al., 2009; Levin et al., 2011) and increased to 80% in 2009 (Long et al., 2012).

In 2011, the National Cancer Institute of Argentina assessed the human and technological resources needed for CRC screening (Instituto Nacional del Cáncer, Ministerio de Salud, 2011). In 2013, CRC screening was established as a priority on the public health agenda, a nationwide CRC screening programme was defined, and national clinical guidelines were developed (Instituto Nacional del Cáncer, Ministerio de Salud, 2017). In addition, standardized diagnostic criteria, treatment and follow-up protocols, guidelines for quality control and quality assurance, training programmes for health professionals, communication strategies, information systems for monitoring, and measurements of programme impact were defined (Instituto Nacional del Cáncer, Ministerio de Salud, 2017). The national CRC screening programme has a coordination centre that is organized into different levels: screening and risk assessment, diagnosis, and treatment of adenomas and cancer (Instituto Nacional del Cáncer, Ministerio de Salud, 2017).

2.3 Latin America

Latin America includes Central America, South America, and the Spanish-speaking countries of the Caribbean: Argentina, Bolivia, Brazil, Chile, Colombia, Costa Rica, Cuba, the Dominican Republic, Ecuador, El Salvador, Guatemala, Haiti, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Puerto Rico, Uruguay, and Venezuela. In recent decades, a few countries in this region, particularly those with the highest CRC mortality rates and with very high or high Human Development Index, have started the process of introducing population-based pilot CRC screening programmes or activities for CRC prevention (Aedo et al., 2016). Only Argentina, Brazil, and Chile have population-based pilot CRC screening programmes, in urban areas; six countries (Columbia, Cuba, Ecuador, Mexico, Puerto Rico, and Uruguay) offer opportunistic screening with clinical guidelines (Table 2.3). Information about screening activities in the other countries is not available (WHO, 2014b).

In 2011, the National Cancer Institute of Argentina assessed the human and technological resources needed for CRC screening (Instituto Nacional del Cáncer, Ministerio de Salud, 2011). In 2013, CRC screening was established as a priority on the public health agenda, a nationwide CRC screening programme was defined, and national clinical guidelines were developed (Instituto Nacional del Cáncer, Ministerio de Salud, 2017). In addition, standardized diagnostic criteria, treatment and follow-up protocols, guidelines for quality control and quality assurance, training programmes for health professionals, communication strategies, information systems for monitoring, and measurements of programme impact were defined (Instituto Nacional del Cáncer, Ministerio de Salud, 2017). The national CRC screening programme has a coordination centre that is organized into different levels: screening and risk assessment, diagnosis, and treatment of adenomas and cancer (Instituto Nacional del Cáncer, Ministerio de Salud, 2017).

FIT, faecal immunochemical test; FS, flexible sigmoidoscopy; gFOBT, guaiac faecal occult blood test; NR, not reported; TC, total colonoscopy.

a Only countries that have implemented a population-based programme or have introduced some recommendations or policies for opportunistic (non-population-based) screening are included.

b Examination coverage: the number of people screened with the recommended test in a given year divided by the number of people eligible for screening (the eligible target population per screening interval) in the same reference year; participation rate (only for population-based organized programmes): the number of people screened divided by the eligible number of people invited to screening during the reference period.

c Examination coverage.

d Participation rate.

e Adults aged 50–69 years who have undergone a stool-based test for blood.
Cáncer, Ministerio de Salud, 2015). The National Cancer Institute of Argentina recommended a two-step population-based CRC screening programme that uses a questionnaire about risk factors to identify high-risk individuals. People in the population aged 50–75 years with no additional background risk are invited to FIT screening, and those with a positive FIT result are referred for colonoscopy. High-risk subjects – individuals with a family or personal history of adenomas, of CRC, or of inflammatory bowel disease – are invited to medical counselling and are referred for the appropriate follow-up, generally colonoscopy (Instituto Nacional del Cáncer, Ministerio de Salud, 2017). According to the Pan American Health Organization, 10–50% of the target population at average risk of CRC has been screened (OPS, 2016).

In 2004, the Brazilian Association for Cancer Prevention started an advocacy programme to promote CRC screening in Brazil (Habr-Gama, 2005). In 2006, the state of São Paulo, under the leadership of the National Cancer Institute of Brazil, developed pilot CRC screening programmes with FIT (Oliva Perez et al., 2008; Prefeitura do Município de São Paulo, 2012).

In 2007, Chile started a prospective multicentre pilot study (PREVICOLON), in which residents of seven major cities aged 50 years and older and without risk factors for CRC were invited to FIT screening, and those with a positive FIT result were referred for colonoscopy (López-Köstner et al., 2012). This study was used as the basis for planning the Prevention Project for Neoplasia of the Colon and Rectum (PRENEC) in collaboration with Tokyo Medical and Dental University (TMDU), and in 2012, the PRENEC project started in three cities (Okada et al., 2016). As a result, colonoscopy training and skills for local physicians improved, and quality indicators also improved over time (Okada et al., 2016). Similar collaborations are being established in other countries, including Brazil, Ecuador, Paraguay, and Uruguay (TMDU International Exchange Site, 2017).

CRC screening activities in the majority of Latin American countries are opportunistic (Table 2.3). Screening with gFOBT or FIT is offered to people older than 50 years, defined as the target population. Some countries are in the process of switching from gFOBT to FIT. In 2013, Colombia defined national CRC clinical guidelines and recommended biennial screening with FIT or screening every 10 years with colonoscopy, when available (Pinzon Florez et al., 2012; Colombia Ministerio de Salud y Protección Social, 2013), but screening coverage is still very low (Colombia Ministerio de Salud y Protección Social, 2015). Cuba has opportunistic CRC screening with good examination coverage (OPS, 2016). In Puerto Rico, in addition to gFOBT, sigmoidoscopy and colonoscopy are also recommended (Schreuders et al., 2015). In Uruguay, an observational prospective study was carried out in an average-risk population to evaluate the feasibility of CRC screening with FIT. A high participation rate of about 90% was achieved (Fenocchi et al., 2006).

2.4 Africa

2.4.1 North Africa

The region of North Africa comprises the following five countries: Algeria, Egypt, Libya, Morocco, and Tunisia.

In November 2017, IARC/World Health Organization (WHO) initiated a pilot demonstration research project, designed to promote participation in FIT screening, in the Rabat region of Morocco. The aim of this project was to evaluate the acceptability and feasibility of CRC screening in the general population setting and to provide guidance on the eventual scaling up of CRC screening to cover the entire country (IARC, 2017).
No other current CRC screening initiative using either endoscopy or stool-based tests for blood was identified by recent surveys that collected information about current CRC screening activities that adopt a population-based approach (Benson et al., 2008), following the International Agency for Research on Cancer (IARC) criteria (Von Karsa et al., 2014), or that include both organized and opportunistic screening (Schreuders et al., 2015; Giordano et al., 2016).

A survey of preventive practices of general practitioners in Morocco reported that only 7% of respondents ordered stool-based tests for blood, compared with a high proportion of physicians who ordered prostate-specific antigen (PSA) screening (El Fakir et al., 2013).

2.4.2 Sub-Saharan Africa

The region of sub-Saharan Africa comprises the following countries: Angola, Benin, Botswana, Burkina Faso, Burundi, Cabo Verde, Cameroon, the Central African Republic, Chad, Comoros, Congo, the Democratic Republic of the Congo, Côte d’Ivoire, Djibouti, Equatorial Guinea, Eritrea, Ethiopia, Gabon, The Gambia, Ghana, Guinea, Guinea-Bissau, Kenya, Lesotho, Liberia, Madagascar, Malawi, Mali, Mauritania, Mauritius, Mozambique, Namibia, Niger, Nigeria, Réunion (France), Rwanda, Sao Tome and Principe, Senegal, Seychelles, Sierra Leone, Somalia, South Africa, Sudan, Swaziland, Togo, Uganda, the United Republic of Tanzania, Western Sahara, Zambia, and Zimbabwe.

No current CRC screening initiative using either endoscopy or stool-based tests for blood was identified by recent surveys that collected information about current CRC screening activities that adopt a population-based approach (Benson et al., 2008), following the IARC criteria (Von Karsa et al., 2014), or that include both organized and opportunistic screening (Schreuders et al., 2015). The lack of current screening initiatives in the sub-Saharan Africa region was confirmed by a literature search performed in PubMed and Embase covering the period from 1 January 2000 to 21 May 2017.

The available data about CRC management are derived mainly from descriptive reports of endoscopy activity, as well as from cancer registries. The studies are usually based on the experience of a single centre, and their size is generally small (only two included > 500 subjects), which limits the generalizability of the reported findings.

Reports of colonoscopy activity, mainly from Nigeria (Onyekwere et al., 2013; Alatise et al., 2014; Akere & Akande, 2017; Ray-Offor et al., 2017) and South Africa (Mahomed et al., 2012), suggest that the quality of endoscopy is suboptimal: the colonoscopy reporting format was not standardized, completion rates varied between 81% and 90%, and the adenoma detection rate was less than 10%, although a lower prevalence of pre-neoplastic lesions could be expected in Africa compared with Europe or the USA. In most regions, colonoscopy facilities are lacking and there are not an appropriate number of well-trained specialists. Low levels of awareness, limited human and financial resources, lack of cancer prevention and control policies, and unaffordability of care contribute to the high CRC mortality rates (Busolo & Woodgate, 2015).

2.5 Central, West, and South Asia

This region comprises Afghanistan, Bahrain, Bangladesh, Bhutan, India, the Islamic Republic of Iran, Iraq, Israel, Jordan, Kazakhstan, Kuwait, Kyrgyzstan, Lebanon, Maldives, Nepal, Oman, Pakistan, Palestine, Qatar, Saudi Arabia, Sri Lanka, the Syrian Arab Republic, Tajikistan, Turkey, Turkmenistan, the United Arab Emirates, Uzbekistan, and Yemen.

The incidence of CRC is relatively low in this region (see Section 1.1). However, in view of the substantial increase in CRC incidence in many of the countries in this region (Arafa & Farhat,
more attention has been paid to prevention and early diagnosis of CRC. Because of financial considerations, in some countries in this region CRC screening focuses on individuals with familial CRC, in particular those with Lynch syndrome. During recent meetings, the Palestinian Society of Gastroenterology and the Mediterranean Task Force for Cancer Control established a network on hereditary CRC, with the goal of improving care for high-risk groups in the Middle East and Mediterranean countries (Ghorbanoghli et al., 2018).

There are very few nationwide organized or pilot programmes for CRC screening in this region (Table 2.4). Bahrain was the first country in the Middle East to implement CRC screening. In 2010, the Bahrain Ministry of Health launched a pilot screening campaign that offered annual screening with FIT to subjects aged 50–90 years (Madan, 2010). In Israel, randomized comparisons of different screening strategies were conducted within established programmes, and a population-based screening programme offering annual screening with FIT to subjects aged 50–75 years was implemented (Levi et al., 2011).

In 2014, the Ministry of Health of Kuwait launched a national pilot CRC screening study that offered biennial screening with FIT to subjects 50 years or older, and in 2016, a total of 70,000 individuals were enrolled (Kuwait Cancer Control Center, 2017). In 2016, the Ministry of Public Health of Qatar launched a national CRC screening programme that offered annual screening with FIT to asymptomatic adults aged 50–74 years (Qatar Ministry of Public Health, 2016).

In 2010, the Health Authority of the United Arab Emirates started a non-population-based programme in Abu Dhabi that advised screening with colonoscopy for people older than 40 years. In 2013, CRC screening with either biennial screening with FIT or screening every 10 years with colonoscopy was offered to subjects aged 40–75 years across the country (Fayadh et al., 2016; Abu Dhabi Health Authority, 2017).

Opportunistic screening is offered in the Islamic Republic of Iran, Lebanon, and Turkey. In 2017, the Ministry of Health of Saudi Arabia launched a pilot screening programme that offers screening with FIT annually for subjects aged 45–75 years (Alsamea et al., 2015; S. Alhomoud, personal communication).

2.6 East and South-East Asia

The region of East Asia includes China, the Democratic People’s Republic of Korea, Hong Kong Special Administrative Region (China), Japan, Mongolia, the Republic of Korea, and Taiwan (China). The region of South-East Asia includes Brunei Darussalam, Cambodia, Indonesia, the Lao People’s Democratic Republic, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and Viet Nam.

Most countries in East Asia are highly developed, have a higher incidence of CRC, and have introduced screening programmes; in contrast, most of the countries in South-East Asia (except Singapore) have a lower incidence of CRC and have no organized screening programmes (WHO, 2014b). The Republic of Korea, Singapore, and Taiwan (China) have national CRC screening programmes, whereas regional pilot screening programmes have been implemented in China, Hong Kong Special Administrative Region (China), and Thailand (Table 2.5). Recommendations for opportunistic screening are available in Brunei Darussalam, Japan, Malaysia, and the Philippines.

In recent years, the Asia-Pacific Working Group on Colorectal Cancer has proposed the Asia-Pacific Colorectal Screening scoring system, to stratify risk on the basis of age, sex, family history, and smoking, for the countries that lack resources and infrastructure (Yeoh et al., 2011). This scoring system serves to determine the risk of CRC and adenomas in asymptomatic...

individuals, to enable the selection of high-risk subjects for CRC screening, and may thus substantially reduce the colonoscopy workload (Chiu et al., 2016); however, it has not yet been widely validated.

2.6.1 East Asia

(a) China

In 2003, China launched the 2004–2010 National Cancer Prevention and Control Program, which included CRC screening as one of the highest priorities for intervention (Kang & Qiao, 2014). In 2006–2008, the Ministry of Health of China implemented a two-step population-based CRC screening programme in the Xiacheng District for adults aged 40–74 years, which provided screening with FIT to high-risk individuals identified through a questionnaire about risk factors, followed by colonoscopy for those with a positive FIT result (Meng et al., 2009). However, because of the large population and limited resources, population-based CRC screening has been implemented only in a small proportion of the target population and covers a limited part of the country (Kang & Qiao, 2014).

(b) Hong Kong Special Administrative Region, China

In September 2016, a CRC screening pilot programme was launched in Hong Kong Special Administrative Region, China, with the aim of evaluating the feasibility of a large population-based organized screening programme. The pilot programme provides subsidized screening with FIT every 2 years for asymptomatic residents of Hong Kong Special Administrative Region, China, born in 1946–1955 (ages 61–70 years), followed by colonoscopy for those with a positive FIT result. People born in 1946–1948 are the first cohort to join the programme, and other age groups will join in subsequent phases (Department of Health of the Hong Kong Special Administrative Region, 2016).

(c) Japan

Since 1983, national screening programmes have been implemented in accordance with the Law of Health and Medical Services for the Elderly, and CRC screening with gFOBT was added in 1992 (Goto et al., 2015). In 2006, the National Cancer Center Japan developed evidence-based guidelines, which are continuously reassessed for policy-making (Hamashima, 2018). CRC screening targets individuals 40 years and older without an upper age limit, and the screening interval is 1 year; FIT has been the most commonly used method of CRC screening (Saito 2006; Goto et al., 2015). In the quality assurance manual for CRC screening, academic societies recommend colonoscopy and CT colonography as the diagnostic examinations after a positive FIT result (Japanese Association of Gastrointestinal Cancer Screening, 2017). All municipalities have to submit their basic screening results to the national government in order to obtain subsidies for the following year. Because there is no official call–recall system and national cancer registries were lacking until 2015, screening in Japan is considered opportunistic. Although most workplaces have also provided CRC screening for employees, specific guidelines were not followed (Hamashima & Yoshida, 2003). In 2015, the participation rate in community-based CRC screening in the municipalities was 13.8% among individuals aged 40–69 years (Ministry of Health, Labour and Welfare, Japan, 2017). In 2015, the combined participation rate in community-based organized screening programmes and opportunistic screening was 41.4% (National Cancer Center Japan, 2017).

(d) Republic of Korea

In the Republic of Korea, the National Cancer Screening Program for CRC, which covers all Korean men and women 50 years or older, began in 2004 (Suh et al., 2017). The National Cancer Screening Program provides annual screening
with FIT as the primary CRC screening method. For individuals who are covered by Medicaid and whose insurance premium is less than the 50th percentile, a free programme is provided by the National Health Insurance Service (Kim et al., 2011). People whose premium is more than the 50th percentile can receive screening with a 20% out-of-pocket payment (Kim et al., 2011). In 2015, a consensus statement developed by a multisociety expert committee recommended annual or biennial screening for adults aged 45–80 years (Sohn et al., 2015). The National Cancer Screening Program is managed and monitored by the National Cancer Center, in cooperation with the National Health Insurance Service. Participants with a positive FIT result are referred for either colonoscopy or a double-contrast barium enema (DCBE) (National Cancer Center Korea, 2015). Colonoscopy or DCBE is performed free of charge at a clinic or hospital designated as a CRC screening unit by the National Health Insurance Service. To improve the quality of screening, the Committee for Quality Assurance published a screening quality guideline in 2009 (Kim et al., 2011). Participation rates in CRC screening increased steadily from 7.3% in 2004 (the first year of the programme) to 25.0% in 2012 (Suh et al., 2017). According to the National Cancer Screening Survey, conducted annually since 2004, the participation rate was 29.1% in 2014 (National Cancer Center Korea, 2015).

(e) Taiwan, China

The government of Taiwan, China, launched a national CRC screening programme in 2004 as part of the National Cancer Control Program (Chen et al., 2004; Yang et al., 2006; Ministry of Health and Welfare Taiwan, 2017). The Health Promotion Administration provided a subsidized CRC screening programme of biennial screening with FIT for citizens aged 50–69 years. Subjects with a positive FIT result were referred for colonoscopy or sigmoidoscopy plus DCBE. In 2004–2009, the nationwide programme used an organized approach for the delivery of screening tests, and FIT kits were distributed to eligible people by public health units in the municipal districts. Approximately 333 units in 25 municipalities nationwide participate in the programme (Chou et al., 2016). In 2010, with special funds for cancer prevention and control obtained after raising the tax on tobacco, the programme was fully subsidized by the government, and the so-called “in-reach screening services” began (Chou et al., 2016). Both organized and opportunistic screening approaches were used, and the number of subjects who underwent CRC screening increased substantially. In June 2013, the age range for screening was expanded to 50–74 years (Health Promotion Administration, Ministry of Health and Welfare, Taiwan, 2016). The local public health bureau in each municipality audited the screening service. The government in collaboration with the academic sector established a surveillance system for a national-level screening database. The examination coverage in 2004–2009 was 21.4% (Chiu et al., 2015) and in 2015 was 42% in people aged 50–69 years (Health Promotion Administration, Ministry of Health and Welfare, Taiwan, 2016). Although the participation rate increased over time, the referral rate for confirmatory diagnostic examinations declined, from 80.0% in 2004–2009 to 53.3% in 2010–2015 (Chou et al., 2016).

2.6.2 South-East Asia

(a) Brunei Darussalam

In Brunei Darussalam, general knowledge about CRC and screening of CRC is relatively poor (Chong et al., 2015). In 2008–2011, the Ministry of Health of Brunei Darussalam conducted a health screening programme that assessed the general health of civil servants and included CRC screening. People 40 years or older were invited to FIT screening, and those with a
positive FIT result were referred for colonoscopy. Of the eligible adults, 66.9% returned their specimens (Chong et al., 2013). Implementing a CRC screening programme was mentioned as one of the priorities in the Brunei Darussalam National Multisectoral Action Plan for the Prevention and Control of Noncommunicable Diseases 2013–2018 (Ministry of Health Brunei Darussalam, 2013).

(b) Malaysia

Malaysia has CRC screening guidelines that recommend gFOBT or sigmoidoscopy for adults 40 years or older; however, there is currently no national organized CRC screening programme. Opportunistic screening is available in private and public hospitals (Academy of Medicine of Malaysia, 2017).

(c) The Philippines

The Philippines Cancer Control Program recommends CRC screening with annual gFOBT and sigmoidoscopy every 3–5 years for people 50 years or older (Ngelangel & Wang, 2002). However, no national programme is in place.

(d) Singapore

The Health Promotion Board of Singapore established CRC screening programmes in July 2011 (Health Promotion Board Singapore, 2017), and the Ministry of Health of Singapore provided practice guidelines for CRC screening (Lee et al., 2010). Annual screening with FIT is recommended for adults 50 years or older; participants with a positive FIT result are referred for further evaluation with colonoscopy (Ministry of Health Singapore, 2017). Before the national programme was implemented, various organizations played an important role in encouraging the public to undergo opportunistic CRC screening. For example, the Singapore Cancer Society has been providing free FIT kits to Singapore citizens and permanent residents 50 years or older (Tan et al., 2013). In September 2017, with enhanced screening subsidies, the government launched the Screen For Life programme to encourage more Singapore citizens to undergo screening and receive the necessary follow-up (Ministry of Health Singapore, 2017). According to the Health Behaviour Surveillance of Singapore, the CRC screening coverage rate was 33.8% in 2013 (Ministry of Health Singapore, 2014). Based on data from the Singapore Cancer Society, the coverage rate of opportunistic screening was 38.9% in 2008 (Tan et al., 2013).

(e) Thailand

In April 2011, Thailand implemented a pilot organized CRC screening programme in Lampang Province for people aged 50–65 years, which provided FIT as the primary screening test and follow-up with colonoscopy through existing government public health services (Khuhaprema et al., 2014). Preliminary results from the pilot study showed a coverage rate of 62.9% in the target population.

Based on the findings of the Lampang Province pilot study, the Thai Ministry of Public Health planned to launch a nationwide CRC screening programme in 2018 (National Health Security Office Thailand, 2017).

2.7 Oceania

This region includes 11 countries: Australia, Fiji, French Polynesia, Guam, Micronesia, New Caledonia (France), New Zealand, Papua New Guinea, Samoa, Solomon Islands, and Vanuatu. CRC screening programmes are well established in Australia and New Zealand (Table 2.6). Apart from these two countries, no organized population-based or opportunistic CRC screening exists in the region (WHO, 2014b).
2.7.1 Australia

After conducting a pilot study in 2002–2004, in 2006 the Australian government introduced the National Bowel Cancer Screening Program, which offered FIT to Australian residents aged 55 years and 65 years (phase 1); all those with abnormal results were referred for appropriate diagnostic evaluation. In 2008, the programme was extended to individuals aged 50–74 years (phase 2) (Young, 2009; Bobridge et al., 2013). The Clinical Practice Guidelines 2017 for the prevention, early detection, and management of CRC recommended biennial screening with FIT for people aged 50–74 years. Screening with colonoscopy is endorsed only for people with a family history of CRC (Australian Government Department of Health, 2017). Currently, the National Bowel Cancer Screening Program provides a free FIT kit to all Australians aged 50–74 years to screening every 2 years with a home FIT kit (Cancer Council Australia, 2018). Of the people invited to screening from January 2014 to December 2015, 39% participated in the programme (Australian Institute of Health and Welfare, 2017).

2.7.2 New Zealand

In New Zealand, since late 2011, the Bowel Screening Pilot study has been offering screening with FIT to eligible people aged 50–74 years living in the Waitemata District Health Board area. The interim evaluation report of the first round of screening (January 2012–December 2013) indicated a participation rate of 56.8% in eligible people (Ministry of Health New Zealand, 2017). Evaluation of the pilot screening programme led to the establishment in 2017 of the National Bowel Screening Programme, which offers free screening with FIT every 2 years to eligible people aged 60–74 years. The programme is being rolled out progressively across all District Health Boards, starting in July 2017 (Ministry of Health New Zealand, 2017).

Colorectal cancer screening

3. STUDIES OF COLORECTAL CANCER SCREENING

3.1 Methodological considerations

Methods for colorectal cancer (CRC) screening include endoscopic methods and stool-based tests for blood. The two primary end-points for endoscopic CRC screening are (i) finding cancer at an early stage (secondary prevention) and (ii) finding and removing precancerous lesions (adenomatous polyps), to reduce the incidence of CRC (primary prevention). The primary end-point for stool-based tests is finding cancer at an early stage. Stool-based tests also have some ability to detect adenomatous polyps; therefore, a secondary end-point of these tests is reducing the incidence of CRC.

3.1.1 Randomized controlled trials of colorectal cancer screening

A randomized controlled trial (RCT) that compares a screening arm with a non-screening arm (or with a screening arm with a different screening modality) is considered the reference standard in evaluating the cancer-preventive effects of a screening test. For screening modalities that only detect cancerous lesions (such as those for breast cancer or lung cancer), the primary end-point of a screening RCT is generally mortality from the cancer of interest. For screening modalities that have the potential to detect and remove cancer precursors (such as those for CRC and cervical cancer), a co-primary end-point of the RCT can be the incidence of the cancer of interest.

The observed effect of screening in RCTs is dependent on, among other things, the participation in the intervention group and the limitation of contamination of the control group. Low participation biases the estimate of effect towards its no-effect value, and therefore it must be evaluated and reported. Screening of controls by services outside of the RCT also dilutes the effect of screening on CRC incidence and/or mortality. If the screening modality being evaluated is widely used in clinical practice in the region or regions where the RCT is being conducted, then contamination may be considerable, although it may be difficult and/or costly to estimate its extent. The standard evaluation of the primary end-point is an intention-to-treat analysis. Methods to adjust for contamination and low participation, called per-protocol analyses, have been proposed (Cuzick et al., 1997; Baker et al., 2002). [Note that these methods differ from those that compare participants who were actually screened with those who were not, which is an invalid method with a high potential for selection bias.]
3.1.2 Observational studies on the preventive effects of colorectal cancer screening

Data from observational studies, in which study participants are not randomly allocated to be screened or not screened, should be used with caution, because of their greater propensity to bias. Comparison of the survival, or stage distribution, of screen-detected cases with that of cases diagnosed outside of screening is notoriously flawed, because of lead-time bias, length-time bias, and overdiagnosis bias. Lead time is the period between when a cancer is found by screening and when it would have been detected from clinical signs and symptoms (not directly observable) in the absence of screening. Survival time, by definition, is measured from the date of diagnosis to the date of death. Lead-time bias is the overestimation of survival time due to earlier detection by screening than clinical presentation; it is very difficult to distinguish from earlier diagnosis leading to a real extension of life. Length-time bias reflects disproportionate detection by screening of indolent tumours, which may reside in a preclinical state for longer time periods than aggressive tumours do. Overdiagnosis is an extreme form of length-time bias in which a tumour that would never have been diagnosed without screening is detected by screening.

Using cohort or case–control designs to compare the mortality and/or incidence rates of a group receiving (or invited to receive) screening with those of a group not receiving (or not invited to receive) screening can avoid the above-mentioned biases, but it will usually involve some type of selection bias, because the decision to be screened is not random and may be related to factors that predispose to, or against, developing the cancer. Careful adjustment for known CRC risk factors may partially alleviate this bias. Cohort studies are generally more reliable than case–control studies for assessing the efficacy of screening, although well-designed case–control studies may be useful. Comparison of the incidence or mortality rates in a screened cohort with concurrent (or past) population rates is also prone to the selection biases described above and may also be biased by variation in temporal and regional trends.

Ecological studies that compare incidence or mortality rates in a region or country where screening has been implemented with rates in the same region or country during a previous time period, or with contemporaneous rates in a neighbouring region or country, may be useful but are subject to the standard caveats of ecological studies.

There are several early observational studies that assessed the effects of endoscopy and stool-based tests for blood on CRC incidence and mortality; most of these studies have major methodological issues. Lead-time bias, length-time bias, selection bias, and confounding factors in these studies could lead to overestimation or underestimation of the effect when not adjusted for. Misclassification of the outcome, CRC incidence or death (ascertainment bias), can also bias the effect estimates. In the Effectiveness of Screening for Colorectal Cancer in Average-Risk Adults (SCOLAR) nested case–control study, Goodman et al. (2015) stressed the challenges in observational studies of colonoscopy screening, including distinguishing between indications for having had a colonoscopy (screening or investigation of symptoms). Some observational studies use, for example, a 6-month window to exclude index examinations that were done to investigate symptoms of CRC.

In light of the published RCTs of sigmoidoscopy screening, the Working Group established two criteria for observational studies to be included in the evaluation of effectiveness: the study (i) must be performed in a screening setting and (ii) must not exclude cancer detected at the baseline endoscopy. Moreover, the Working Group established six considerations to weigh the impact of individual studies on the overall estimate: (i) there must be a concurrent control
group, (ii) there must be an adequate length of follow-up, (iii) the sample size must be large enough to detect relevant effects, (iv) the study must be conducted in a setting with contemporary methods, (v) the outcome (and exposure) ascertainment must be reliable, and (vi) potential confounder data must be available and adjusted for in the analysis.

3.1.3 Evaluation of the adverse effects of colorectal cancer screening

An adverse effect of screening is defined as any negative effect on individuals or populations that results from being involved in the screening process compared with not being involved in screening. It is important to quantify not only the frequency of the harm but also its magnitude. It is also important to recognize that the harms in an RCT may be different from the harms in a screening programme.

(a) Definitions of harms

Harris et al. (2014) proposed a taxonomy of the harms of screening. They proposed four domains of harms: physical effects, psychological effects, financial strain, and opportunity costs. Financial strain and opportunity costs [the indirect effect of screening on health-related activities] are not considered in this review. Here, harms are classified on the basis of where in the screening cascade they occur: harms associated with (i) the screening process, (ii) the screening test itself, and (iii) the management of a positive screening result.

Potential harms of the screening process include anxiety, caused by the invitation to screening or awaiting the results of screening, and a negative impact on lifestyle or health-seeking behaviour. The assessment of these outcomes requires validated instruments and is best conducted as a longitudinal study over the course of screening, ideally as part of an RCT, comparing individuals invited to screening with those not invited to screening.

It is possible that reassurance from a negative screening result (whether true-negative or false-negative) could lead to delay in presentation for investigation of symptoms that develop in the interval between scheduled screening tests, with consequent late diagnosis of an interval cancer and possibly death from it. Such an impact on mortality would form part of the overall mortality measured in the screening arm of an RCT of CRC screening and would not be measurable separately from it. However, its presence within the results of the RCT would remove any need to account for it separately when estimating a benefit–harm ratio from the RCT.

No physical harms are incurred with stool-based tests for blood. Potential harms of endoscopic tests include pain, physical damage to the bowel due to endoscopy, possible hospitalization, and the need for surgical repair. The frequency and severity of such harms can be estimated from a representative screened cohort.

Potential harms associated with the management of a positive screening result include physical harm from the workup and treatment and harm from the psychological response to knowledge of the result and any aspect of its management. Apart from the possible harms of treating a screen-detected cancer, the harms experienced are largely independent of whether the screening result is true-positive or false-positive. Some people restrict the definition of a true-positive to invasive cancer, whereas others include advanced adenoma in the definition, and still others may include detection and removal of precancerous lesions (polypectomy).

(b) Overdiagnosis

An overdiagnosed cancer is defined as a cancer detected as a result of screening that would not have been diagnosed if screening had not taken place. The lower the pathological grade of a screen-detected cancer and the shorter
the individual’s life expectancy at the time the cancer is diagnosed, the more likely it is that the cancer is an overdiagnosed cancer. The harm associated with overdiagnosis comes from labelling the individual as a cancer patient and from any adverse effects of the treatment of the cancer.

(i) Quantification of overdiagnosis

Screening that leads to the earlier diagnosis of cancer will always cause an apparent increase in cancer incidence, some of which is due to advancing the time of diagnosis of cancers that would have been diagnosed anyway, and some of which is due to overdiagnosis. To quantify overdiagnosis accurately, it would be necessary to follow up identical screened and unscreened cohorts until the rise in the cancer incidence rate in the screened cohort has stabilized, and then stop screening and continue to follow up the cohorts until the cancer incidence rates are approximately the same in the screened and unscreened cohorts. The total excess rate of cancer in the screened cohort is then the rate of cancer overdiagnosis. In practice, such a quantification process is rarely possible, although it could be approximated by a well-done RCT that adopts most of the above-mentioned features. There are various other ways to estimate overdiagnosis, but few or none that are likely to produce a highly accurate result ([Carter et al., 2015; Ripping et al., 2017; Davies et al., 2018]).

When quantifying overdiagnosis, one may consider it (i) as a cumulative lifetime risk of overdiagnosis associated with participation in screening; (ii) as the ratio of the cumulative rate of overdiagnosis to the cumulative rate of cancer in unscreened individuals, expressed as a percentage; (iii) as the percentage of cancers in screened individuals that are overdiagnosed; or (iv) as the percentage of screen-detected cancers that are overdiagnosed. In a screening programme that also prevents cancer (via detection and treatment of precursors), so that screened people have a lower cumulative rate of diagnosis of cancer than unscreened people, it is practically impossible to determine whether some of the screen-detected cancers are overdiagnosed cancers. Although the reduction in cancer incidence indicates a clear benefit, some harm from the detection and treatment of precancerous lesions that would never have become symptomatic invasive cancers in the person’s lifetime is also likely.

There are three types of harms of overdiagnosis as usually defined: (i) labelling of an individual as a cancer patient (which may cause anxiety and lead to problems obtaining health insurance and life insurance); (ii) the immediate side-effects of treatment; and (iii) the long-term consequences of diagnosis, including, for example, intensive surveillance. Quantification of these harms is an important contributor to obtaining an accurate estimate of the balance of benefits and harms of screening. Each of these types of harms will apply to some degree to the detection and treatment of simple polyps or adenomas at varying degrees of advancement during the course of screening for CRC.

(ii) Overdiagnosis of precancerous lesions

The proportion of polyps that would cause symptoms if not removed is low but increases as one moves from non-adenomatous polyps to non-advanced adenomas and to advanced adenomas (including multiple non-advanced adenomas). The Working Group could not agree about whether to use the term overdiagnosis to include simple polyps, non-advanced adenomas, or even adenomas. Some felt that it should be possible to estimate how many adenomas would not have progressed to cancer and that this number should be reported as being overdiagnosed. (That group did not wish to attempt to quantify how many adenomas may have been diagnosed in the absence of screening, as a result of colonoscopies in response to bowel symptoms.) Other Working Group members felt that the term overdiagnosis was not helpful and that
it was more appropriate to report the number of polyps, non-advanced adenomas, and advanced adenomas and the consequences of each of those diagnoses. It was agreed that the frequency of detection of polyps, non-advanced adenomas, and advanced adenomas should be reported, as should the consequences of such detection, including potential harms and their frequency.

There was a lack of agreement among Working Group members about whether some or all of the harms associated with treatment of these precancerous lesions should be attributed to screening.

3.1.4 Interval cancers

An interval cancer is defined as a cancer that is diagnosed between routine screens, that is, cancers diagnosed after a positive screening test that were not diagnosed as a result of that screening test. Thus, interval cancers are cancers that were missed by screening or by investigation after a positive screening test, or that have developed since the most recent screening test was done.

For most screening, the interval cancer rate will depend on the screening interval: the shorter the interval, the smaller the chance of developing an interval cancer. For this reason, it may be useful to consider cancers diagnosed $x$ years after a negative screening result (where $x = 1, 2, 3, \ldots$) and to censor the follow-up when the individual is next screened. The interval cancer rate may also be higher after the first screen than it is after subsequent screens, because of the higher prevalence of cancer at the time of the first screen and a consequently higher risk of an incident cancer in the first interval between screens.

Although interval cancers are considered by some people to be a harm of screening, they are better conceived of as a lack of benefit due to the (probably unavoidable) imperfect sensitivity of the test. There is no suggestion that an interval cancer would not also have been diagnosed in the absence of screening. Nonetheless, interval cancers are an indicator of test insensitivity, and if the interval cancer rate in the screened population is greater than the quality assurance benchmark for the test, reasons for this performance deficiency should be sought and addressed.

3.1.5 Benefit–harm ratio and cost–effectiveness

Screening should be implemented only if its benefits outweigh its harms and if the financial resource requirements are reasonable in relation to the net benefit of screening (i.e. if screening is cost-effective).

(a) Benefit–harm ratio

All forms of screening are associated with both benefits and harms. The updated sets of criteria for screening published by the World Health Organization (Andermann et al., 2008) and the United States Preventive Services Task Force (Harris et al., 2011) both explicitly mention the balance between benefits and harms as a decisive criterion for the implementation of a screening intervention. The difficulty with this criterion is how to objectively weigh the benefits and harms of screening, because they are measured differently. How much harm is acceptable for every CRC death, or every incident CRC case, that can be prevented by screening? A growing number of studies consistently find that the attributes of screening tests, such as efficacy, process, and cost, are significant determinants of the choice of implementing a screening programme and of the screening method (Mansfield et al., 2016).

Informed decisions with respect to screening can be aided by giving people considering screening an outcomes table, which presents quantitative information about all potential benefits and harms of screening, so that people can decide whether they want to participate in screening. Such an outcomes table is a useful tool for patient information, but governments or guideline-issuing institutes still need to
determine for the population as a whole whether the benefit–harm ratio is favourable. This can be done simply, but subjectively, by committee consensus or, more objectively, by translating benefits and harms into summary measures of health benefit or harm, such as quality-adjusted life years (QALYs) or disability-adjusted life years (DALYs) gained or lost (see below). This has been done very rarely.

(b) Cost–effectiveness

QALYs and DALYs are two summary measures of health or life gained or lost that can be used to estimate the net outcome of health interventions. They each incorporate years of life and quality of the life in a single measure. QALYs are a measure, in the aggregate, of the gain or loss of life of a group subject to the intervention weighted by a measure of the quality of the life. Quality of life, for this purpose, is generally measured in terms of a person’s ability to carry out the activities of daily life, free of pain and mental disturbance, with a weight of 1 for fully able and a weight of 0 for totally unable. One DALY can be thought of as one lost year of disability-free life, where years of life lost to death have a weight of 1 and years of life lived free of any disability have a weight of 0, with the experience of a group measured in DALYs aggregated, as described above for QALYs.

To extrapolate outcomes from RCTs to lifetime QALYs and DALYs, mathematical models are typically used to track the benefits and harms of the intervention, accounting in the QALY weights used for any adverse effects of the intervention that intervention-arm participants experienced, taking account of the deaths, aggregating the QALYs or DALYs in each arm, and calculating the difference between the two arms as the net benefit of the intervention expressed as QALYs gained or DALYs averted, each of which can be expressed as positive or negative values.

Cost–effectiveness analysis formally compares the health outcomes with the economic costs of different interventions, thereby assisting decision-makers to identify the interventions that will yield the greatest health benefits, given their resource constraints (Cantor, 1994). The costs that are considered depend on the perspective but generally include not only those of the intervention itself (in this case, screening) but also those of diagnostic follow-up and workup and adverse effects. Potential longer-term savings from treatment leading to prevented cases of disease (or advanced disease) are also included. The results of a cost–effectiveness analysis are summarized in an incremental cost–effectiveness ratio. The QALYs gained or DALYs averted with a particular strategy (in this Handbook, a CRC screening prevention programme) compared with an alternative strategy (no CRC screening programme) are included in the denominator, and the additional (incremental) costs of that strategy (compared with the same alternative) are included in the numerator, yielding an incremental cost per DALY averted or per QALY gained (Cantor, 1994). Future costs and benefits of the intervention are usually discounted to their present value (Sanders et al., 2016).

To ensure efficient use of resources, the cost–effectiveness of an intervention such as screening should be compared not only with the situation without screening but also, if applicable, with alternative screening interventions. For example, the costs and effects of endoscopic screening should be compared with those of stool-based screening strategies, and the costs and effects of 10-yearly endoscopy should be compared with those of single endoscopy. The incremental cost–effectiveness ratio is also used for this comparison.

The World Health Organization principles for population screening state that screening should be implemented only when there is a good balance between costs and benefits (Wilson & Jungner, 1968). Unfortunately, there is no universal definition of “good balance”; for example, in the USA an intervention that provides an additional year
of life at an incremental cost of US$ 100 000 per life year gained has been accepted as a reasonable balance between costs and effects (Weinstein, 2008). The National Institute for Health and Care Excellence in the United Kingdom considers interventions with an incremental cost–effectiveness ratio of less than £20 000 per QALY gained to be cost-effective (NICE, 2013). Interventions with cost–effectiveness ratios in the range of £20 000 to £30 000 per QALY gained can still be considered acceptable, depending on additional criteria, whereas interventions costing more than £30 000 per QALY gained are generally not considered to be cost-effective. The World Health Organization has suggested using cost–effectiveness thresholds of 1–3 times the annual per capita gross domestic product of the country (WHO, 2014). Such an approach is particularly relevant in cost–effectiveness studies for CRC screening (see Sections 3.2.6, 3.3.6, and 3.5.4), which have been performed mostly in high-income countries. Consequently, the findings with respect to costs and benefits of screening may be very different in low- and middle-income countries, which generally have lower background cancer risks, different cost levels, and vastly different abilities to pay.

(c) Using cost–effectiveness analyses to determine age limits and intervals for screening

Cost–effectiveness analyses can address more than just the question of whether a certain intervention is cost-effective. RCTs are the reference standard for evaluation of the effectiveness of interventions; however, only a limited number of strategies can be evaluated in RCTs, whereas the number of different potential strategies is endless. Screening strategies can differ in the test modality used, the age at which to begin screening, the age at which to end screening, and the screening interval. Valid cost–effectiveness models offer the opportunity to extrapolate beyond the observations in the RCTs and assess and compare alternative intervention strategies in an efficient way. Furthermore, such models can estimate the budget and resource impact of these strategies, so that only strategies that are feasible in a particular setting can be considered. For example, for the implementation of the CRC screening programme in the Netherlands, cost–effectiveness modelling had shown that the most cost-effective screening strategy to implement was faecal immunochemical test (FIT) screening with a low cut-off level for a positive test (Wilschut et al., 2011a). However, in case of limited colonoscopy capacity, the modelling indicated that the most cost-effective alternative would be to offer FIT screening with a higher cut-off level for a positive test (Wilschut et al., 2011b).

3.2 Stool-based tests for blood

3.2.1 Techniques

(a) Introduction

Faecal occult blood tests (FOBTs), used as primary tests for CRC screening, are based on the detection of gastrointestinal occult blood in stool (Young et al., 2015; Schreuders et al., 2016). However, CRC and precancerous lesions are not the only sources of blood in faeces. In addition to other conditions (e.g. inflammatory bowel disease or colitis), other lesions such as haemorrhoids, hyperplastic polyps, and diverticular disease can lead to blood in the stool (Digby et al., 2013). The probability that FOBTs will detect gastrointestinal bleeding depends on the anatomical site of the bleeding, patient characteristics (transit time of faeces, consistency of faeces, degradation of haemoglobin [Hb] in the intestine), and factors that affect the bleeding of gastrointestinal lesions (intermittent bleeding) (Ahlquist et al., 1989); in addition, factors intrinsic to the test, such as its capacity to detect the activity or the presence of the Hb molecule or other blood constituents, will influence the detection of bleeding (Young et al., 2015). Depending on the origin of the bleeding, faeces will contain Hb, haem, or the globin moiety at different degradation stages (Rose et al., 1989; Young et al., 1990; Rockey et al., 1999).

Recently, a stool-based test combining DNA with a faecal immunochemical component has been developed for CRC screening (see Section 3.7.1).

(b) Methods and equipment

(i) gFOBT

The guaiac FOBT (gFOBT) was developed at the beginning of the 20th century by the German gastroenterologist Boas (Boas, 1914). gFOBT was the first test to be widely used for CRC screening and to be evaluated in RCTs (see Section 3.2.2). gFOBT detects blood by the use of paper impregnated with guaiac, which is extracted from the wood resin of Guaiacum trees, to which hydroperoxidase is added. When it comes into contact with haem (but not exclusively), the hydroperoxidase oxidizes guaiac, leading to a blue colour that is evaluated as a qualitative result (positive or negative for the presence of blood). The standard gFOBT consists of three paper cards, each with two panels, requiring sampling from three separate faeces samples (Schreuders et al., 2016). gFOBT can be analysed with or without rehydration. gFOBT does not detect Hb concentrations of less than approximately 600 µg Hb/g faeces; when gFOBT is rehydrated, the analytical sensitivity is higher, but more false-positive results are obtained (Tinmouth et al., 2015). One manufacturer has developed a high-sensitivity gFOBT (HSgFOBT) with performance similar to that of rehydrated gFOBT (Allison et al., 1996). Results of gFOBT are read with the naked eye, which leads to a subjective evaluation. Results are not quantifiable using automated instrumentation and are therefore not suited to high-throughput screening programmes.

(ii) FIT

FIT for Hb was developed in the late 1970s by the clinical pathologist Barrows. The method was based on using goat anti-Hb antibodies and demonstrated improved sensitivity and specificity compared with gFOBT in the detection of small amounts of Hb in faeces (Barrows et al., 1978). FIT detects the globin moiety of human Hb by immunoassay methodology using different methods. Two of the most widely used methods are lateral flow immunochromatography (qualitative) and immunoturbidimetry (quantitative) (Phalguni et al., 2015). FIT can detect human blood with high analytical sensitivity (Rockey, 1999), which ranges from 1 µg to 300 µg Hb/g faeces, depending on the FIT characteristics and the manufacturer. However, FIT does not usually detect small quantities of blood from the upper gastrointestinal tract (i.e. above the stomach),
because it is degraded by digestive proteolytic enzymes (Rockey et al., 1999).

In qualitative FIT, each manufacturer can adjust the conditions of the analysis at a specific concentration of Hb. Quantitative FIT has a detection limit that ranges from 6 μg to 50 μg Hb/g faeces. FIT typically relies on samples in which faeces are collected using specimen sampling devices designed for direct processing on analysers; this allows for high-throughput, standardized methodology and therefore decreases performance variability (Tinmouth et al., 2015).

The concentration of faecal Hb associated with colonic lesions increases along the adenoma–carcinoma sequence, from normal mucosa to hyperplastic polyps through to non-advanced polyps and then from advanced polyps to carcinoma (Carroll et al., 2014). Several studies have shown that there is an association between Hb concentration and the detection of colorectal neoplasia (Liao et al., 2013; Auge et al., 2014; van Doorn et al., 2015; Chen et al., 2016). Therefore, the performance of quantitative FIT depends on the cut-off level used to define a positive test result. If the FIT cut-off level is increased, fewer but more advanced lesions will be detected and fewer colonoscopies will be required (Allison et al., 2014). By using quantitative FIT, screening programmes can choose the faecal Hb cut-off level appropriate to their resources (Halloran et al., 2012; Allison et al., 2014).

(c) Technical factors that affect FOBT results and quality control

(i) gFOBT

In gFOBT, any dietary Hb or myoglobin (e.g. from meat, especially if raw or half-cooked) as well as drugs or foods that have peroxidase properties (e.g. some uncooked fruits and vegetables, such as cabbage and green beans) can potentially lead to a positive test result, although there is no consistent evidence that positivity rates differ substantially between gFOBT participants with or without restrictions of those foods (Rozen et al., 1999; Pignone et al., 2001). In contrast, antioxidants in drugs or foods (e.g. vitamin C or vitamin E) have the potential to lead to a negative test result by interfering with the oxidation of guaiac (Jaffe et al., 1975; Müftügil, 1985; Allison et al., 2014). There is no consistent evidence of medications with anticoagulant properties, such as aspirin, non-steroidal anti-inflammatory drugs, or warfarin, causing positive gFOBT results in individuals without disease (Norfleet, 1983; Greenberg et al., 1996, 1999; Kahi & Imperiale, 2004; Clarke et al., 2006) or altering the positive predictive value of gFOBT (Sawhney et al., 2010; Lee et al., 2012; Gandhi et al., 2013). Finally, the dark-green or black appearance of faeces in patients treated with iron supplements, antacids, or antidiarrhoeal treatments with bismuth can be confounded with the blue colour of a positive gFOBT (Laine et al., 1988; Rockey, 1999).

Factors that can affect gFOBT reading include interobserver variability, reproducibility of reads by laboratory personnel (Niv, 1990; Fleisher et al., 1991; Selinger et al., 2003), temperature, the design of the gFOBT card, the colour of the laboratory walls, and the brightness of the artificial lighting (Halloran et al., 2012).

Professional external quality assessment schemes are unusual, and internal quality control is usually restricted to a performance monitor feature included in the gFOBT cards. Staff training, including double reading of positive results, has a large effect on the reliability and validity of interpretation (Rabeneck et al., 2008).

(ii) FIT

FIT is analytically sensitive to low concentrations of all types of intact human Hb (excluding fetal Hb) and therefore has a significantly improved analytical specificity, avoiding cross-reactivity with dietary Hb as well as other dietary components (Allison et al., 2014).
Quantitative FIT is becoming the most commonly used stool-based method for CRC screening (Schreuders et al., 2015). Many different quantitative FIT devices are commercially available; they vary in collection method, Hb stability, analytical methodology, polyclonal or monoclonal antibody characteristics, or calibration material. One of the major differences among the FITs from different manufacturers is that they use different faecal sample collection devices, which vary in the amount of faeces collected and the volumes of preservation buffers used (Fraser et al., 2012). The observed/apparent discrepancies in diagnostic performance of quantitative FITs can be largely reduced by adjusting the cut-off level to provide specific positivity rates or defined levels of specificity (Gies et al., 2018).

Manufacturers of automated quantitative FITs provide an internal quality control, and participation in an external quality assessment scheme is particularly important for national screening programmes in which different laboratories are involved (Halloran et al., 2012). Another important issue that must be taken into account is the sample quality. The globin moiety (detected with FIT) is less stable than the haem moiety (detected with gFOBT); therefore, proteolysis of globin should be avoided between sample collection and analysis. Samples show good stability at refrigerator temperatures but marked deterioration with rising temperature. Samples refrigerated at 4 °C showed no significant degradation over a period of 21 days (daily degradation, 0.3% ± 0.4%), whereas with storage at 28 °C a daily degradation of 3.7% ± 1.8% was shown (Vilkin et al., 2005; Rozen et al., 2006; Halloran et al., 2012). A decrease in positivity, a lower detection rate, and a loss of clinical sensitivity have been reported during seasons with high temperatures (van Roon et al., 2012; Doubeni et al., 2016). Manufacturers invest effort in developing new preservation buffers to improve stability, but sample conservation still represents a challenge to the organization of FIT-based screening programmes. Table 3.2.1 summarizes the main characteristics of gFOBT and FIT.

(d) Screening performance

Screening performance refers to the ability of the test to detect cancer and to distinguish cancer from non-cancer conditions. The ultimate effectiveness of CRC screening tests depends on their performance within a screening programme, i.e. across multiple rounds of testing and the complete screening episode in subjects who

|-----------------------------------|-----------------------------------|
| gFOBT                             | FIT                               |
| Chemical reaction                 | Immunochemical reaction           |
| Nonspecific for human haemoglobin | Specific for human haemoglobin    |
| Larger faecal specimen            | Smaller faecal specimen           |
| Cumbersome specimen collection    | Less cumbersome specimen collection|
| Qualitative                       | Qualitative or quantitative       |
| Subjective interpretation of test results | Objective interpretation of test results |
| Manual analysis                   | Automated analysis (high-throughput) |
| Basic quality control procedures  | Advanced quality control procedures|
| Nonspecific for lower intestinal tract | Higher analytical specificity for lower intestinal tract |
| Lower sensitivity and detection rate for advanced neoplasia | Higher sensitivity and detection rate for advanced neoplasia |

FIT, faecal immunochemical test; gFOBT, guaiac faecal occult blood test.
successfully complete diagnostic follow-up of positive test results.

Wide ranges of sensitivities of gFOBT (any type) for the detection of CRC and advanced adenomas have been described (Table 3.2.2). For FIT (any type), the pooled sensitivity and specificity for the detection of CRC (based on a meta-analysis) have been estimated to be 79% (95% confidence interval [CI], 69–86%) and 94% (95% CI, 92–95%), respectively (Lee et al., 2014). However, different sensitivities and specificities have been reported using different FIT strategies (Table 3.2.3). Several studies conducted in average-risk screening populations have shown that the sensitivity of FIT is higher than that of gFOBT in detecting both CRC and advanced neoplasia.

Another important issue for stool-based tests for blood is the cumulative performance over multiple screening rounds. A study conducted in Italy in the context of a FIT-based screening programme in the population aged 50–69 years

gFOBT, guaiac faecal occult blood test; HSGFOBT, high-sensitivity gFOBT.
showed, after five rounds of biennial screening, cumulative detection rates for CRC (0.85%) and advanced adenoma (5.9%) similar to those reported in one round of primary screening with colonoscopy between screens in a programme in Italy (subjects aged 50–69 years; 0.85% for CRC and 5.9% for advanced adenoma) and in a trial in the USA (subjects aged 50–84 years; 0.7% for CRC and 7.6% for advanced adenoma or sessile serrated lesions ≥ 1 cm) (Zorzi et al., 2018). These data suggest that the efficacy of FIT screening is closely related to the cumulative sensitivity of repeated tests; therefore, comparisons between FIT and other screening strategies should not be based on a single round of FIT. For quantitative FIT, a study showed that, after 5 years of follow-up, participants with a FIT result of between 8 µg and 10 µg Hb/g faeces (below the established cut-off level for positivity) had a significant 8-fold higher cumulative incidence of advanced neoplasia than those with a baseline of undetectable faecal Hb (Grobbee et al., 2017a). A study in Taiwan, China, reported an increase in the risk of interval cancer with increasing concentrations of faecal Hb, with relative risks ranging from 1.6 in those with concentrations of 50–99 µg Hb/g faeces to 2.9 in those with concentrations higher than 149 µg Hb/g faeces (Chiu et al., 2017). Information about the comparison of the performance of gFOBT versus FIT in relation to the detection rate of advanced neoplasia is summarized in Section 3.4.2.

(e) Additional factors that affect performance

The ability of stool-based tests to detect faecal blood is closely related to the characteristics of the colorectal lesions as well as their localization. Because sessile serrated lesions are typically flat, non-ulcerated, and without haemorrhagic features, FOBTs fail to detect these lesions (Heigh et al., 2014), and because of their low prevalence, they are unlikely to represent a suitable target for FOBT-based screening programmes (Zorzi et al., 2017). In relation to the localization, Brenner et al. (2017) reported a higher sensitivity of FIT in the detection of advanced adenomas in the distal colon (44%; 95% CI, 38–51%) than in the proximal colon (20%; 95% CI, 14–28%).

Faecal Hb concentration varies with sex and age; it is higher in older people and in men (McDonald et al., 2011). Variations are also seen across countries and even between neighbourhoods in the same city; these differences are related to the level of socioeconomic deprivation (Fraser et al., 2014, 2015; Buron et al., 2017). FOBT performance differs between men and women (Brenner et al., 2010a). Using FIT with the same cut-off level for both sexes results in a higher sensitivity and a lower specificity for advanced colorectal neoplasia in men than

in women (Grobbee et al., 2017b). Regardless of these differences, screening programmes currently use the same strategies for both sexes in relation to the cut-off level and the screening intervals. Adjusting cut-off levels on the basis of age and sex could contribute to the efficacy of FIT-based CRC screening programmes and optimize the use of available endoscopy resources.

3.2.2 Randomized controlled trials

(a) Descriptions of RCTs

Five RCTs on screening with gFOBT have been published. The characteristics of these trials are presented in Table 3.2.4.

In the Minnesota trial, which started in 1975, 46 551 participants aged 50–80 years were randomly assigned to CRC screening once a year, to screening every 2 years, or to a control group (Mandel et al., 1993). Participants were recruited from among volunteers for the American Cancer Society and other groups in Minnesota, USA. Participants submitted six guaiac-impregnated paper slides (the Hemoccult test) containing twosmears from each of three consecutive stools. The slides were mailed to a central laboratory for testing, and because of the potential for drying (and associated decrease in sensitivity of the test) caused by delays in mail delivery, the slides were rehydrated with a drop of water during processing, beginning in 1977. This procedure was fully implemented in 1982 and was used until the end of trial screening (82.5% of slides rehydrated). Participants with one or more slides that tested positive were advised to undergo diagnostic evaluation. Initially, this was with rigid sigmoidoscopy or single-contrast barium enema, which was replaced with colonoscopy in 1978.

In contrast to the Minnesota trial, the other four RCTs did not have an annual screening arm, and the slides were rehydrated in only one of those trials.

In the Nottingham trial, 152 850 individuals, identified from general practice registers in Nottingham, United Kingdom, were randomly assigned to biennial screening with Hemoccult (two samples from each of three consecutive stools) or to a control group (Hardcastle et al., 1996). Controls were not told about the study. A repeat test was sent to individuals with up to four slides that tested positive. To limit false-positive rates, those individuals were advised to restrict their diets for 2 days before taking two samples from each of three consecutive stools. Only participants with five or more slides that tested positive on the first test and those with one or more slides that tested positive on the repeat test were advised to undergo colonoscopy.

In the Funen trial, 137 485 residents of Funen, Denmark, identified from the population register of Funen County, were randomized to biennial screening with Hemoccult II, to a control group, or to not be enrolled in the study (Kronborg et al., 1996). Controls were not told about the study and continued to use health-care facilities as usual. Participants were asked to provide two samples from each of three consecutive stools. Individuals with one or more slides that tested positive were invited for colonoscopy.

In the Gothenburg trial, 68 308 residents of Gothenburg, Sweden, aged 60–64 years in three cohorts (those born in 1918–1922, 1923–1927, and 1928–1931) were randomized to screening with Hemoccult II or to a control group (Kewenter et al., 1994). A second screening round was offered 16–24 months after the initial round. Participants were asked to provide samples on 3 days. The slides were rehydrated, except those from participants born in 1918–1920. The results from the three cohorts were pooled. Participants in the 1928−1931 cohort with a positive test result on the first or second screening were retested with Hemoccult II, and only those with a positive result on the retest were invited for workup. This included an interview with a physician to determine whether the participant had experienced abdominal symptoms or rectal bleeding in the previous 6 months. A rectal examination,

b 82.5% of the slides were rehydrated.
c [91.7%] of the slides were rehydrated.
d This value should probably be 362 492, as the sum of 181 210 and 181 282 (see text).
proctoscopy, sigmoidoscopy, and double-contrast barium enema were performed. Those with a negative workup were retested again with three Hemoccult II slides. Then those with one or more slides that tested positive underwent colonoscopy (Kewenter et al., 1988).

In Finland in 2004–2012, while the national CRC screening programme was being implemented, men and women aged 60–69 years were randomized to be invited or not to biennial CRC screening with gFOBT without rehydration. A total of 181 210 subjects were allocated to the screening arm and 181 282 to the control arm, covering 43.5% of the target population in Finland aged 60–69 years at the end of 2012 (Malila et al., 2008; Pitkäniemi et al., 2015).

(b) Results of RCTs

The published results on CRC mortality and incidence of the most recent follow-ups of the five RCTs are shown in Table 3.2.5.

For the Minnesota trial (Shaukat et al., 2013), after a mean follow-up of 30 years, the cumulative CRC mortality rate was 42 per 100 000 person-years in the annual screening group (200 deaths; 1.8%) and 50 per 100 000 person-years in the biennial screening group (237 deaths; 2.2%), compared with 63 per 100 000 person-years in the control group (295 deaths; 2.7%). Screening reduced CRC mortality (relative risk [RR], 0.68; 95% CI, 0.56–0.82 with annual screening; RR, 0.78; 95% CI, 0.65–0.93 with biennial screening). In stratified analyses, reductions in CRC mortality in the biennial screening group were significantly larger in men than in women (RR, 0.63; 95% CI, 0.48–0.82 in men; RR, 0.92; 95% CI, 0.72–1.18 in women). In addition, reductions in CRC mortality were largest in men aged 60–69 years compared with men younger than 60 years or older than 70 years \( (P_{\text{interaction}} < 0.04) \). An earlier publication from the Minnesota trial, on CRC incidence after 18 years of follow-up, reported cumulative CRC incidence ratios of 0.80 (95% CI, 0.70–0.90) in the annual screening group and 0.83 (95% CI, 0.73–0.94) in the biennial screening group (Mandel et al., 2000). [The Working Group noted that the reduction in CRC incidence in this RCT could be attributed to greater referral to colonoscopy among the participants because of a higher positivity rate for gFOBT with rehydration.]

For the Nottingham trial (Scholefield et al., 2012), after a median follow-up of 19.5 years, the cumulative CRC mortality rate was 91 per 100 000 person-years (1176 deaths) in the biennial screening group, compared with 100 per 100 000 person-years (1300 deaths) in the control group. Screening reduced CRC mortality (RR, 0.91; 95% CI, 0.84–0.98). There was no significant difference in the reductions in CRC mortality in men and women separately or in those younger than 60 years compared with those 60 years or older. There was no significant difference in CRC incidence between the screening group and the control group (RR, 0.97; 95% CI, 0.91–1.03).

For the Funen trial (Kronborg et al., 2004), after 17 years of follow-up (1985–2002), the cumulative CRC mortality rate was 84 per 100 000 person-years in the biennial screening group (362 deaths), compared with 100 per 100 000 person-years in the control group (431 deaths). Screening reduced CRC mortality (RR, 0.84; 95% CI, 0.73–0.96). CRC incidence was similar in the screening group and the control group (RR, 1.02; 95% CI, 0.93–1.12).

For the Gothenburg trial (Lindholm et al., 2008), after 9 years of follow-up, the cumulative CRC mortality rate was 53 per 100 000 person-years in the biennial screening group (252 deaths), compared with 64 per 100 000 person-years in the control group (300 deaths). Screening reduced CRC mortality (RR, 0.84; 95% CI, 0.71–0.99). There was no difference in CRC incidence between the screening group and the control group (RR, 0.96; 95% CI, 0.86–1.06).

In the Finnish screening programme (Pitkäniemi et al., 2015), after a median follow-up of 4.5 years, the cumulative CRC mortality rate

was 21.1 per 100,000 person-years in the biennial screening group (170 deaths), compared with 20.4 per 100,000 person-years in the control group (164 deaths). There was no reduction in CRC mortality (RR, 1.04; 95% CI, 0.84–1.28) or in CRC incidence (RR, 1.11; 95% CI, 1.01–1.23) as a result of screening.

(c) Results of meta-analyses of RCTs

The results of the four published meta-analyses of RCTs on the efficacy of CRC screening with gFOBT are shown in Table 3.2.6. The first meta-analysis was published in 1998 (Towler et al., 1998), and the most recent was published in 2016 (Fitzpatrick-Lewis et al., 2016). Three of the meta-analyses (Towler et al., 1998; Hewitson et al., 2008; Fitzpatrick-Lewis et al., 2016) included the results from the Minnesota, Nottingham, Funen, and Gothenburg trials described in Table 3.2.4, although Fitzpatrick-Lewis et al. (2016) included only the annual screening arm of the Minnesota trial and excluded 875 subjects whose records were not traceable in the Office for National Statistics database at the time of the analysis.

(d) FIT

There is only one cluster randomized trial that evaluated FIT screening and CRC mortality in rural China (Zheng et al., 2003; Fitzpatrick-Lewis et al., 2016). In 1989, residents aged 30 years and older from 21 townships in Jiashan County were enrolled in the trial. The residents were randomized to a screening group (10 townships) or to a control group (11 townships), which did not undergo screening. The screening and control townships were matched by age and population size into 10 pairs. Participants in the screening group completed a single FIT based on reverse passive haemagglutination. Participants with a positive FIT result underwent sigmoidoscopy.
or colonoscopy. There were 94,423 participants in the screening group and 97,838 individuals in the control group. Duration of follow-up was 5–6 years, and causes of death in 1989–1996 were certified by qualified physicians. At the end of the study period, 361 deaths from CRC had occurred in the screened group and 357 in the control group. There was no significant difference in CRC mortality between the screened group and the control group (RR, 0.88; 95% CI, 0.72–1.07). [The Working Group noted that the limitations of this trial included enrolment of younger people and short follow-up.]

3.2.3 Observational studies on preventive effects

This section summarizes the observational studies assessing the preventive effects of screening with gFOBT or FIT versus no screening, with CRC mortality and/or CRC incidence as an outcome. Studies that compare gFOBT with FIT in terms of the detection rates of adenoma, neoplasia, or CRC are summarized in Section 3.4.2.

(a) Cohort studies

A total of nine cohort studies (including a nested case–control study) conducted in China, Denmark, Finland, France, Italy, Japan, Scotland, and Taiwan, China, have reported on CRC mortality and/or CRC incidence after screening with gFOBT or FIT, mostly in the age group 50–69 years (Table 3.2.7).

(i) gFOBT

A nested case–control study with annual gFOBT screening after age 40 years and matched for age, sex, and family history of both CRC and adenomas was conducted in Italy in 1978–1995. A large but non-significant reduction in CRC mortality was reported (odds ratio [OR], 0.64; 95% CI, 0.36–1.15) for attenders (ever screened) versus non-attenders (never screened). Also, the reduction in CRC mortality increased with the number of screening tests: having two or three tests reduced the risk by 29%, whereas having four or more tests reduced the risk by up to 66% (Bertario et al., 1999).

In a pilot study conducted in Finland, the population aged 50–63 years from three municipalities in southern Finland was invited to screening. A total of 1785 individuals were screened only once with a gFOBT developed in Finland (Malila et al., 2007). After 25 years of follow-up, no effects on CRC mortality or CRC incidence were observed compared with the general Finnish population, in terms of standardized mortality and incidence rates. The pilot study was stopped after one screening round, because of costs and low specificity. [The Working Group noted as limitations that this was a small population with only one round of screening, the participation rate was high (69%), and the positivity rate of the gFOBT used was higher than in other studies, i.e. 19%.

The large matched cohort study by Libby et al. (2012) included the Scottish arm of the United Kingdom pilot of gFOBT screening, which covered individuals resident in three Scottish National Health Service Boards (Steele et al., 2009). The pilot consisted of three rounds of biennial gFOBT screening carried out in more than 379,655 individuals aged 50–69 years. Follow-up was up to 10 years, and the overall screening participation was 60.6%. A 10% relative reduction in CRC mortality was reported with an intention-to-screen analysis comparing those invited versus those not invited to screening (RR, 0.90; 95% CI, 0.83–0.99), and a 17% relative reduction was reported after adjusting for participation (RR, 0.83; 95% CI, 0.79–0.87). [The Working Group noted that the reported 95% confidence interval of the mortality relative risk adjusted for participation appeared to be too narrow and recalculated it to be 0.74–0.92. Although the effect appeared to be stronger in men and in younger age groups, the Working Group attributed this to

CI, confidence interval; CRC, colorectal cancer; FIT, faecal immunochemical test; gFOBT, guaiac faecal occult blood test; HR, hazard ratio; IRR, incidence rate ratio; OR, odds ratio; RR, relative risk; SIR, standardized incidence ratio; SMR, standardized mortality ratio; vs, versus; yr, year or years.
a possible lack of statistical power.] The reduction in CRC mortality started from approximately 4 years after initial screening.

In a study conducted in 12 districts of Burgundy, France, residents aged 45–74 years were invited to biennial gFOBT screening. The average participation rate in the first round was 52.8%. A significant reduction of 13% in CRC mortality was observed after 11 screening rounds compared with CRC mortality in the population in 17 non-screened districts (standardized mortality ratio [SMR], 0.87; 95% CI, 0.80–0.94) [the Working Group calculated the participation-adjusted SMR (0.74; 95% CI, 0.63–0.86)], whereas no difference in the CRC incidence rate was observed (standardized incidence ratio [SIR], 1.01, 95% CI, 0.96–1.06) (Hamza et al., 2014).

An incidence-based mortality cohort study (Bjerrum et al., 2016) was conducted in Denmark in 2005–2006 (the study design was published in Lindebjerg et al., 2014), to assess whether participation in once-only gFOBT screening has an effect on CRC incidence and mortality. The study included 182,152 citizens aged 50–74 years (166,277 screened), and the participation rate was 48.5%. After a median of 8.9 years of follow-up, CRC mortality was lower in the screened group compared with the reference group of Danes of the same age (hazard ratio [HR], 0.92; 95% CI, 0.86–0.99). [The Working Group calculated the participation-adjusted HR for CRC mortality (0.82; 95% CI, 0.70–0.95).] A negative association with all-cause mortality was also reported (HR, 0.95; 95% CI, 0.94–0.96). Because CRC mortality and all-cause mortality were almost the same, the authors could not conclude that one round of gFOBT screening had an effect on reducing CRC mortality. CRC incidence was also lower in the screened group compared with the population in the rest of Denmark (adjusted HR, 0.94; 95% CI, 0.90–0.97). [The Working Group calculated the participation-adjusted HR for CRC incidence (0.74; 95% CI, 0.63–0.86). The Working Group highlighted as limitations that the study evaluated only one screening round and that it did not adjust for pre-screening differences in health status between the compared groups.]

(ii) FIT

Ventura et al. (2014) compared CRC mortality and incidence between two cohorts in Italy. One cohort was screened biennially with FIT for up to 11 years after the first screening round (average, 3.6 FITs), and the other cohort was unscreened (defined as those who had been invited to screening but did not comply with the first round). The study reported lower CRC mortality (SMR, 0.59, 95% CI, 0.37–0.93) and lower overall incidence (HR, 0.78; 95% CI, 0.65–0.93) in the attenders versus the non-attenders. [Some contamination in the reference group is likely in this study, with individuals who would not have attended the first round but attended the subsequent rounds. However, the direction of this potential bias would be towards the null effect.]

In a screening programme in northern Italy, launched in 2005, residents aged 50–69 years were invited to screening with biennial FIT (Giorgi-Rossi et al., 2015). After four screening rounds, the study reported a reduction of 36% in incidence-based CRC mortality (RR, 0.64; 95% CI, 0.52–0.78) compared with a historical non-screened cohort in the same area. A decrease of 10% in CRC incidence was observed after 8 years in the screened cohort compared with the control cohort (incidence rate ratio, 0.90; 95% CI, 0.83–0.97). [Data needed for the calculation of the participation-adjusted RR were not available in the published literature.]

In a study by Chiu et al. (2015), the first million individuals aged 50–69 years (20% of the target population) in Taiwan, China, were screened with biennial FIT, and the average follow-up was 3 years. The study reported a 62% decrease in CRC mortality (RR, 0.38; 95% CI, 0.35–0.42) in the screened group versus the invited but unscreened group, which resulted
in a 10% decrease (95% CI, 0.84–0.95) when adjusted for self-selection bias and increasing CRC incidence trends in Taiwan, China. [The Working Group noted that follow-up was short, leading to a possible length-time bias, and that the cumulative CRC mortality in the unscreened group could indicate that individuals previously diagnosed with CRC may have been included, leading to an overestimation of the magnitude of the effect.]

(iii) gFOBT/FIT

Jin et al. (2013) performed a study at Beijing Military General Hospital, China, in 1987–2005. A total of 3863 army officers older than 50 years were screened with annual gFOBT. Those with a positive gFOBT result completed FIT, and those with a positive FIT result were referred for colonoscopy. After 21 years of follow-up, the study reported a relative risk of CRC mortality of 0.36 (95% CI, 0.18–0.71) and a relative risk of CRC incidence of 0.51 (95% CI, 0.30–0.87). [The Working Group considered that this was a very small population in which to evaluate CRC mortality.]

(b) Case–control studies

Case–control studies can complement the results from RCTs and help to address questions related to screening efficacy and frequency (Weiss, 2013).

A total of six case–control studies, in France, Italy, Japan, and the USA, have been published that assessed CRC mortality-associated odds ratios in screened versus unscreened individuals. In addition, some reported mortality trends in relation to (i) the number of screening rounds and (ii) the time since the last screen (Table 3.2.8).

(i) gFOBT

Three studies were published in the USA between 1993 and 1999 (Selby et al., 1993; Lazovich et al., 1995; Scheitel et al., 1999). All three reported a decrease in CRC mortality with gFOBT screening (annual or biennial), ranging from 28% to 31%. Also, in one study, the magnitude of the reduction in CRC mortality was significantly larger after four rounds of biennial screening compared with one, two, or three rounds of screening (Scheitel et al., 1999). In addition, Lazovich et al. (1995) observed a significant reduction in CRC mortality only in those aged 74 years and younger at diagnosis of CRC.

In a study in Italy, Zappa et al. (1997) reported an odds ratio for CRC mortality of 0.60 (95% CI, 0.4–0.9) comparing ever screened versus never screened (205 cases and 1030 controls). The reduction in CRC mortality decreased with an increasing number of years since the most recent screening test.

A study conducted in France was published in 1999 (Faire et al., 1999) and updated in 2014 (Hamza et al., 2014; see Section 3.2.3(a)). This population-based case–control study (178 cases and 712 population-based controls) reported an odds ratio for CRC mortality of 0.64 (95% CI, 0.46–0.91) for individuals screened with biennial gFOBT versus non-screened individuals, as well as decreasing CRC mortality with an increasing number of screening rounds ($P_{\text{trend}} = 0.03$). No significant reduction in CRC mortality was observed more than 24 months after the most recent round of screening.

(ii) FIT

Two case–control studies were conducted in the same region in Japan. One evaluated FIT screening and CRC mortality (Saito et al., 1995), and the other reported on FIT screening and CRC stage distribution (Nakajima et al., 2003).

Saito et al. (1995) reported a significant reduction of 60% in CRC mortality in those screened within 1 or 2 years of the case diagnosis compared with those who were unscreened; the reduction in CRC mortality decreased after 3 years and became non-significant after 4 or more years. The authors also reported trends of

increasing CRC mortality with time since the last screen [no \( P_{\text{trend}} \) was reported].

In a subsequent analysis in a subset of the same population, Nakajima et al. (2003) reported that subjects who had undergone at least one FIT screen during the previous 4 years had a reduced risk of developing advanced CRC (stage T2 to T4) by 28–46%, compared with those who were unscreened. The odds ratios for developing advanced cancer within 2–5 years after FIT were lower for the rectum (OR, 0.32–0.73) than for colon (OR, 0.84–1.18).

(iii) gFOBT and FIT

An additional case–control study in Japan showed a large reduction in CRC mortality based on only 28 CRC cases (Hiwatashi et al., 1993). [The Working Group excluded this study from the evaluation primarily because of the sample size limitations and the use of a mixture of gFOBT and FIT screening.]

(c) Ecological studies

Two ecological studies conducted in Italy compared CRC mortality and incidence in late screened areas versus early screened areas within the same geographical regions. Both of these studies reported reductions in CRC mortality (Table 3.2.9). [The Working Group considered that these results should be interpreted with caution because of limitations in study design.]

The first ecological study covered individuals aged 40–69 years in two regions in Tuscany, Italy: the Empolese–Mugello district, where screening with biennial gFOBT or FIT started in 1980 (early screened regions), and the provinces of Florence and Prato, where screening was implemented in 1985–2006 (late screened regions) (Costantini et al., 2008). The reduction in CRC mortality was larger in the early screened regions than in the late screened regions: the estimated annual percentage decrease in the age-adjusted CRC mortality rate was 2.7% (95% CI, 1.7–3.7%) in the early screened regions and 1.3% (95% CI, 0.8–1.7%) in the late screened regions. [The Working Group noted that gFOBT was used until 1996, and FIT later.]

The second ecological study evaluated the impact of a biennial FIT-based screening programme implemented in 2002–2009 in Veneto, Italy, for residents aged 50–69 years, by comparing early screened areas, where screening started in 2002–2004, with late screened areas, where screening was implemented in 2008–2009 (Zorzi et al., 2015). Before the implementation of screening, CRC mortality and incidence rates in the two areas were similar. Compared with 1995–2000, the 2006–2011 CRC mortality rates were 22% lower in the early screened areas than in the late screened areas (RR, 0.78; 95% CI, 0.68–0.89), and the mortality reduction was larger in women than in men. A substantial increase in the percentage of stage I CRCs detected by screening was observed in 2006 (> 50%) compared with no screening programme in 2000–2001 (12%), which could explain the observed reduction in mortality rates in the population in the early screened areas. [A possible limitation of this study is the contamination in the late screened areas by the presence of opportunistic screening before the introduction of the organized screening programmes.]

(d) Meta-analyses

A meta-analysis of both RCTs and observational studies evaluated the effects of gFOBT screening on CRC mortality (Elmunzer et al., 2015). Overall, the study reported a reduction of 18% in CRC mortality \((n = 17; \text{RR, 0.82; 95\% CI, 0.76–0.88})\) and a significant reduction of 20% when only observational studies were included \((n = 12; \text{RR, 0.80; 95\% CI, 0.71–0.91})\).

A recent meta-analysis included 44 studies (both RCTs and observational studies) published in 1992–2016 and evaluated the effects of five different CRC screening methods (gFOBT, FIT, sigmoidoscopy, colonoscopy, and a combination of sigmoidoscopy plus gFOBT) (Zhang

et al., 2017). When gFOBT was compared with no screening in a total of 19 studies including 2,264,603 participants, the meta-analysis reported a reduction of 14% in CRC mortality (RR, 0.86; 95% CI, 0.82–0.90), and a statistically non-significant reduction in CRC incidence, based on nine studies (RR, 0.99; 95% CI, 0.96–1.03). When FIT was compared with no screening in three observational studies (two cohort studies and one case-control study), the same meta-analysis reported a reduction of 59% in CRC mortality (RR, 0.41; 95% CI, 0.29–0.59), and a reduction of 21% in CRC incidence, based on only two studies (RR, 0.79; 95% CI, 0.69–0.92). [The Working Group noted the mixture of experimental and observational study designs included in this meta-analysis, which limits its interpretation in terms of effectiveness. Also, in the pooled estimate of FIT, one observational study in a non-screened Japanese population was included.]

3.2.4 Adverse effects

This section considers the harms of screening with stool-based tests for blood, from observational studies and RCTs. One might consider three sources of harms: harms attributable to the process of screening per se, harms directly attributable to the test, and harms of managing individuals with a positive screening result. These harms can be psychological harms or physical harms.

(a) Psychological harms

Parker et al. (2002) sent the 30-question General Health Questionnaire (a self-administered instrument for identifying minor psychiatric disorders in the general population) to 2,184 people 1 month before gFOBT screening and to 1,693 people 3 months after screening. Among the 843 people who completed both questionnaires, there was no significant difference in the proportion showing probable psychiatric morbidity before and after screening. The same study compared suicides among all randomized individuals in the Nottingham trial of gFOBT-based CRC screening (Hardcastle et al., 1996). There were 48 [0.06%] suicides among 74,998 controls compared with 53 [0.07%] among 75,253 people invited to screening. [The Working Group noted that the percentages reported in the article are slightly different, so either the absolute numbers or the percentages in the article must be incorrect, but this would not affect the similarity between the two groups.]

Laing et al. (2014) carried out surveys at 7–14 days and at 4 months after gFOBT screening and assessed short-term situational anxiety (using the State-Trait Anxiety Inventory) (Spielberger et al., 1983), frequency of CRC-specific worry, and mood disturbance. At 7–14 days after screening, 55 respondents with positive screening results had higher situational anxiety (mean score, 38.8) compared with 110 respondents with negative screening results matched on age and sex (mean score, 30.9; \( P_{\text{difference}} = 0.007 \)). Respondents with positive screening results were also nearly 4 times as likely to report CRC-related mood disturbances compared with respondents with negative screening results (RR, 3.82; 95% CI, 1.09–13.43). [The Working Group noted the small sample size of the study.] There was a non-significant increase in the frequency of colon cancer-specific worry (based on answers to the question, “How often do you worry about getting colon cancer?”) in those with positive screening results. At 4 months after receipt of the screening result, both situational anxiety and mood disturbance (in both groups) had returned to baseline (pre-screening) levels.

Lindholm et al. (1997) sent a questionnaire to individuals invited to participate in the Gothenburg trial of gFOBT screening (Kewenter et al., 1994). A total of 2,932 participants completed the questionnaire, and 16% of them reported that they were very worried or extremely worried when they received the invitation. Subsets of participants were also interviewed by telephone. Of the 156 participants interviewed after
receiving a positive gFOBT result, 60% were very worried or extremely worried after they received that result. Of the 96 participants with a negative result on a second gFOBT, only 4% remained very worried or extremely worried after they received their second result.

In another study, Mant et al. (1990) identified 56 individuals who had received a positive gFOBT result followed by a negative gFOBT result or colonoscopy. Using a structured questionnaire, they interviewed 54 of them about their experience (e.g. “How distressed were you at the initial result?”). Two thirds reported some degree of distress after the initial positive result, but of those, only 14% were very distressed.

In the study by Parker et al. (2002), anxiety scores (using the State-Trait Anxiety Inventory) were highest after notification of a positive gFOBT result (mean scores of 44) but fell immediately after notification of a negative colonoscopy (mean scores of 31). [The Working Group noted that these findings highlight the importance of prompt follow-up of positive findings, to minimize the duration of anxiety.]

(b) Physical harms of FOBT tests

There are no reports of physical harms directly associated with FOBT screening. Theoretically, one might imagine that poor hygiene associated with FOBT procedures could lead to the spread of gastrointestinal infections, but there are no published studies of such harm.

(c) Physical harms of follow-up treatment

This section considers (i) harm done while investigating a positive screening result and (ii) harm done by the treatment of an overdiagnosed CRC.

To assess the harm done while evaluating a positive screening result, one might simply consider the proportion of those screened who have a positive test result and the harms of investigating such a result. Most FOBT-positive subjects are referred for colonoscopy. Good data are available on the harms associated with screening colonoscopy (see Section 3.3.4), but fewer data are available about the harms of triage colonoscopy (i.e. colonoscopy as a result of a positive FOBT screening result). Apart from discomfort (from both the bowel preparation and the endoscopy itself), the main harms are the risks of serious bleeding, perforation of the bowel, and other serious complications leading to hospitalization. The nature of the harms is the same as with screening colonoscopy, but the frequencies of such harms are different, because
FOBT-positive subjects are more likely to require a polypectomy (Rao et al., 2009).

Table 3.2.10 presents serious harms from colonoscopy in studies of FOBT-based screening expressed as major events per 10 000 screens. Table 3.2.10 includes both RCTs and reports from routine screening programmes. [The Working Group calculated the harms per 10 000 screens. The Working Group found it difficult to ascertain how many screens were carried out in some of the studies, and approximated those from the numbers of colonoscopies and the screening positivity in some cases.] The studies had a varying number of screening rounds (range, 1–11). Based on 11 CRC screening studies (four RCTs, five programmes or pilot programmes, and two cohort studies), the colonoscopy rate (test positivity, expressed as colonoscopies per 100 screens) for stool-based testing for blood ranges from 1.0% to 8.5%, and up to 9.8% if considering the rehydrated slides of the Mandel et al. (1993) trial only. The serious harms generally increased in studies with a larger proportion receiving colonoscopy. In the reports of the two largest programmes, each with more than half a million screens (Steele et al., 2009; Logan et al., 2012), the combined rate of serious adverse events was less than 1 per 10 000 screens. Higher rates of bleeding were reported in a regional programme in France (Denis et al., 2013) and in one small study in Spain (Quintero et al., 2012), and higher rates of perforations were reported in an early trial from Sweden (Kewenter & Brevinge, 1996). In the four studies (with a total of nearly 2 million FOBT screens and 30 000 colonoscopies) that reported on deaths from colonoscopy, there were none.

(d) False-positive results

Often the frequency of the harm of a positive screening result is expressed in terms of the harm of a false-positive screening result (on the grounds that there is no real harm associated with a true-positive screening result). There is then a question about what constitutes a false-positive screening result. Given that most authors would say that the aim of FOBT is to diagnose cancer earlier, a false-positive result would be a positive test result in an individual who does not have CRC. However, many authors consider a positive test result in the presence of an advanced adenoma to be a true-positive, and some would consider it to be a true-positive if there was any adenoma.

(e) Overdiagnosis

The four RCTs of gFOBT with individual randomization all reported on CRC incidence, and none of them showed any evidence of net overdiagnosis. For the Funen trial (Kronborg et al., 2004), the relative incidence was 1.02 (95% CI, 0.93–1.12) over 17 years. For the Gothenburg trial (Lindholm et al., 2008), it was 0.96 (95% CI, 0.86–1.06) over up to 19 years. For the Nottingham trial (Scholefield et al., 2012), it was 0.97 (95% CI, 0.91–1.03) after a mean of 17 years. Scholefield et al. (2012) included a graph of cumulative incidence, which was initially larger in the screening arm, but the curves crossed at 5 years. In contrast, the Minnesota trial (Mandel et al., 2000) showed a reduction in CRC incidence ratios of 0.80 (95% CI, 0.70–0.90) for the annual screening arm and 0.83 (95% CI, 0.73–0.94) for the biennial screening arm (see Section 3.2.2). The cumulative CRC incidence curves in the screening and non-screening arms crossed at 7 years. [The Working Group concluded that depending on the sensitivity of the stool-based tests, there would be overdiagnosis of CRC if screening were to be offered to individuals with less than 5–7 years of residual life expectancy.]

(f) Harms related to the detection of adenomas

The potential harms of detection of adenomas (whether or not they are overdiagnosed) include the effects of labelling the individual as a patient, the effects of adenoma removal, and the effects of
Table 3.2.10 Serious harms from colonoscopy after a positive stool-based test for blood

offering more intensive surveillance for individuals with advanced adenomas. The serious harms of polypectomy (such as causing major bleeding or perforation) are described and quantified in Section 3.3.4.

3.2.5 Benefit–harm ratio of FOBT screening

(a) Background

This section describes the balance between benefits and harms (i.e. benefit–harm ratio) of CRC screening with stool-based tests for blood, based on data from modelling studies that included both endoscopy and stool-based testing for blood, as well as additional studies that only presented results on gFOBT or FIT. The benefits and harms of CRC screening with stool-based tests for blood have been discussed previously (see Section 3.2.2, Section 3.2.3, and Section 3.2.4). The value of FOBT screening can be measured with life years gained (LYG) or QALYs gained. Both are common measures used in health economics, and they translate to the benefit (years of life) and harms and burdens (quality of life) a person may receive as a result of screening. It is important to note that there is not necessarily a standard for how these quality adjustments are included for different studies. Therefore, it is important for authors to carefully define the terms and for readers to understand them.

(b) Systematic reviews of life years gained

The United States Preventive Services Task Force (USPSTF) updated its review for CRC screening in 2016 (Bibbins-Domingo et al., 2016). A systematic literature review (Lin et al., 2016) and a modelling decision analysis (Knudsen et al., 2016) informed the USPSTF review. The modelling was from the three CRC microsimulation models of the Cancer Intervention and Surveillance Modeling Network (Knudsen et al., 2016) (see Table 3.3.14 in Section 3.3.5).

The USPSTF reviewed the current established tests of colonoscopy, sigmoidoscopy, HSGFOBT, and FIT and the emerging tests of computed tomography (CT) colonography and multitarget stool DNA (mt-sDNA). The evidence supported with high certainty that CRC screening provided benefit that is substantially larger than its harms (i.e. there is high certainty that the net benefit is substantial). Here, LYG for gFOBT, HSGFOBT, and FIT are discussed, compared with no screening (comparison between CRC screening tests is addressed in Section 3.4; see text and tables). In the decision analysis for the USPSTF, the LYG with screening for individuals at average risk aged 50–75 years for annual FIT were 231–260 LYG per 1000 individuals aged 40 years and required 1739–1899 colonoscopies (diagnostic and surveillance) per 1000 individuals screened in a lifetime. These numbers amount to a ratio of 6.7–8.5 colonoscopies per LYG. The efficiency ratio (the ratio of incremental colonoscopies per additional LYG compared with a less intensive strategy) varied from 17 to 24 colonoscopies per LYG. The LYG with screening for individuals at average risk aged 50–75 years for annual HSGFOBT were 232–261 LYG per 1000 individuals aged 40 years and required 2230–2287 colonoscopies (diagnostic and surveillance) per 1000 individuals screened in a lifetime. These numbers amount to a ratio of 8.5–9.8 colonoscopies per LYG. These results suggest that FIT and HSGFOBT with 100% participation can achieve comparable LYG, but that the repeated FIT over 25 years requires considerably fewer colonoscopies.

(c) QALYs and DALYs from modelling studies

This section reviews modelling studies on CRC screening with gFOBT (including HSGFOBT) and FIT. There are 18 studies that have evaluated the impact of FIT and gFOBT screening on QALYs (Table 3.2.11). All of the studies concluded that CRC screening influenced QALYs positively and resulted in a net gain in
QALYs. QALYs gained by screening with gFOBT varied from 2 QALYs per 1000 (Sharp et al., 2012) to 131 QALYs per 1000 (Lam et al., 2015) and up to 486 QALYs per 1000 (Wong et al., 2015) for a population with polyps. When screening with FIT, the net benefit was slightly higher than that for gFOBT, varying from 4 QALYs per 1000 (Dan et al., 2012) to 801 QALYs per 1000 (Wong et al., 2015) for a population with polyps. In those studies where both gFOBT and FIT were included, QALYs gained for FIT were higher than QALYs gained for gFOBT. [The wide variability across studies could be from different assumptions for the model inputs or definition of QALYs, and the Working Group highlighted that internal comparisons are more useful than comparisons across studies. In addition, the variability in estimates can be partly explained by the age of the population to which the estimates were standardized and by different strategies for intervals between screens.]

Only three modelling studies reported their results as DALYs averted for the impact of gFOBT (Table 3.2.12). Ginsberg et al. (2010) considered three regions (East Africa, eastern Europe, and the Americas), and the results ranged from 1.8 DALYs per 1000 individuals in East Africa to 17.8 DALYs per 1000 individuals in the Americas. For an Australian population at average risk aged 55–69 years, Stone et al. (2004) reported 1.5 DALYs per 1000 individuals for biennial gFOBT. For women in Hong Kong Special Administrative Region, China, Woo et al. (2007) reported 7 DALYs per 1000 individuals for annual FOBT and 3 DALYS per 1000 individuals for biennial FOBT.

3.2.6 Cost–effectiveness studies

(a) Background

A screening test can provide high value if its health benefits justify its cost. Determining what the justification boundaries are will vary according to the patient, the payer, the hospital, and even policy measures. From a payer perspective, a typical cost–benefit level in the USA is US$ 100 000 per LYG, whereas lower levels are used elsewhere. Moreover, costs for CRC screening depend on the screening test and strategy used.

Costs for the FOBT strategies can include the test itself, evaluation of each test, subsequent diagnostic colonoscopy for positive FOBT test results with potential pathology costs for evaluation of polyps, surveillance colonoscopy for patients with adenoma, and potential cancer treatment. Administrative costs for FOBT screening, including repeat testing (annually or biennially), processing of the test with reporting back to the primary care provider and to the patient, and scheduling those with positive test results for colonoscopy, are not commonly included in the cost structure, even though there are significant costs associated with the administration of a stool-based test for blood (Heitman et al., 2010; Pignone et al., 2011). Even “no screening” has an associated cost, which is the cost of treating cancers that arise symptomatically in the population. The FOBT tests themselves have limitations; not all positive test results are true positives, and not all negative test results are true negatives. For FIT, the cut-off level for positivity can be varied to accommodate the colonoscopy capacity for screening for a given area.

(b) Cost–effectiveness studies and systematic reviews

In 2000, only a few years after the publication of the results from several RCTs showing CRC mortality reduction with gFOBT screening, Helm et al. (2000) estimated the cost–effectiveness of the Minnesota trial (Mandel et al., 1993), the Nottingham trial (Hardcastle et al., 1996), and the Funen trial (Kronborg et al., 1996). Based on the European trials, gFOBT screening cost US$ 2500 per LYG compared with no screening. In 2004, Whynes et al. (2004) followed up the 1996 Nottingham trial of gFOBT with a

CRC, colorectal cancer; FIT, faecal immunochemical test; FOBT, faecal occult blood test; gFOBT, guaiac FOBT; NR, not reported; QALYs, quality-adjusted life years; yr, year or years.

\(^a\) Includes studies published after Patel & Kilgore (2015) (for studies within and outside the USA and studies in the USA) or after Lansdorp-Vogelaar et al. (2011) (for studies in the USA).

\(^b\) Signifies the population at the start of the simulation, i.e. cohort age 50 years signifies a population of people aged 50 years that are followed up until death or a certain age, and cohort age 50–75 years signifies a population of people aged 50–75 years that are followed up until death or for a certain period. None of the studies considered the anxiety associated with screening and diagnostic follow-up or the potential negative impact of a negative screening test result on an unhealthy lifestyle in their estimates of QALYs.

\(^c\) In Heitman et al. (2010), “FOBT-high” was erroneously labelled “FOBT-low”. To correct this issue, the published “FOBT-low” values were assigned to the “FOBT-high” category listed in this table, and the published “FOBT-high” values were assigned to the “FOBT-low” category listed in this table.

\(^d\) FIT with a cut-off level of 200 ng Hb/mL.

CRC, colorectal cancer; DALYs, disability-adjusted life years; gFOBT, guaiac faecal occult blood test; yr, year or years.

¹ Signifies the population at the start of the simulation, i.e. cohort age 50 years signifies a population of people aged 50 years that are followed up until death or a certain age, and cohort age 50–75 years signifies a population of people aged 50–75 years that are followed up until death or for a certain period.
cost–effectiveness analysis. Under conservative assumptions, the cost of screening in the Nottingham trial was £1584 (US$ 2582) per LYG as a result of screening. These studies suggested that gFOBT screening had an acceptable cost for the benefit gained.

Three systematic reviews on the cost–effectiveness of gFOBT or FIT compared with no screening have been published (Pignone et al., 2002; Lansdorp-Vogelaar et al., 2011; Patel & Kilgore, 2015) (Table 3.2.13). Pignone et al. (2002) included seven cost–effectiveness studies, five of which included gFOBT. Given the time period of the review, only the lower-sensitivity gFOBT was included. All studies found gFOBT to be cost-effective, with costs ranging from US$ 5691 to US$ 17 805 per LYG. Lansdorp-Vogelaar et al. (2011) reviewed 22 modelling studies that included gFOBT strategies scheduled either annually or biennially. The cost per LYG ranged from cost savings to US$ 56 300 per LYG. [As noted above, internal comparisons of gFOBT are more informative than comparisons across the different modelling groups.] The studies in Patel & Kilgore (2015) overlapped with those in Lansdorp-Vogelaar et al. (2011) but included five additional studies for gFOBT or FIT (Vijan et al., 2001; Parekh et al., 2008; Knudsen et al., 2012; Dinh et al., 2013; Ladabaum et al., 2014; see Table 3.2.14). All gFOBT CRC screening strategies assessed were more cost-effective than no screening.

Since the review by Patel & Kilgore (2015), two new models have been published that evaluated the cost–effectiveness of CRC screening in the USA (Kingsley et al., 2016; Barzi et al., 2017) and one in the Republic of Korea (Lee & Park, 2016). One model has published updated results (Ladabaum & Mannalithara, 2016) (Table 3.2.14). The findings of these studies are consistent with those of Patel & Kilgore (2015). These newer studies often included evaluations of both gFOBT and FIT. Kingsley et al. (2016) and Barzi et al. (2017) demonstrated cost savings for annual FIT and gFOBT. Since the review by Lansdorp-Vogelaar et al. (2011), 14 new studies have been published that evaluated the cost–effectiveness of gFOBT or FIT screening outside the USA: three in Canada (Heitman et al., 2010; Telford et al., 2010; Goede et al., 2017), four in Europe (Sharp et al., 2012; Whyte et al., 2012; Pil et al., 2016; Aronsson et al., 2017), and seven in Asia (including the Middle East) (Barouni et al., 2012; Dan et al., 2012; Wang et al., 2012; Lam et al., 2015; Wong et al., 2015; Lee & Park, 2016; Sekiguchi et al., 2016), showing that FOBT screening was predominantly cost saving (Table 3.2.13).

Table 3.2.14 summarizes the cost–effectiveness for the studies presented in the previous

* Currency conversion method: the given currency was converted into United States dollars based on the conversion rate on 1 January of the publication year.

* FIT with a cut-off level of 200 ng Hb/mL.
paragraph. All studies found that FOBT screening was either cost saving or below US$ 31 500 per LYG [costs were presented as published and also standardized to United States dollars of the year in which the study was published]. These results with cost estimates also showed wide variability. Screening with FIT annually had higher QALYs gained than screening with FIT biennially but required more screening resources. Strategies with wider age ranges screened also had higher QALYs gained but required more resources. The cost–effectiveness of FOBT screening has been evaluated across the world, with reports from Asia, Europe, and North America showing benefit with acceptable levels of cost. Given the wide variation in costs across countries and studies, the cost per LYG from different studies can only be compared qualitatively.

(c) Comparison of cost–effectiveness of FIT versus gFOBT

The modelling studies also estimated the cost–effectiveness (or comparative effectiveness) of FIT and gFOBT (see Section 3.4.3).

A next step is to assess whether there are optimal strategies that balance LYG and resources required. Strategies to consider are the screening test, intervals of rescreening, and age groups for screening.

The Cancer Intervention and Surveillance Modeling Network provided a decision analysis for the USPSTF, based on three different microsimulation models (Knudsen et al., 2016), to inform the USPSTF review for different CRC screening tests in the population at average risk, starting at age 50 or 55 years and ending at age 75, 80, or 85 years for those with consistently negative screening results since starting screening. Repeat intervals of 1, 2, or 3 years were considered for FOBT. The USPSTF is not allowed to use costs per se. Instead, the number of colonoscopies required (per 1000 individuals aged 40 years) for the process of screening (with surveillance for patients with adenoma) over the ages screened on the horizontal axis. The line connecting the strategies on the outer envelope of data points represents strategies that provide the largest incremental increase in LYG per additional colonoscopy required for that strategy. This line is called the efficient frontier. Efficient screening strategies are on the efficient frontier, and near-efficient strategies have LYG within 98% of the efficient frontier. The strategies on the efficient frontier are all acceptable choices provided the resources required are available. Fig. 3.2.1 shows the efficient frontier for FIT and HSGFOBT screening. When evaluated together, the FIT strategies comprised almost all points on the efficient or near-efficient frontier. In addition, under the assumption of higher sensitivity and specificity of FIT relative to HSGFOBT, the FIT-based screening strategies provide more LYG for each level of colonoscopy resources across all age groups and repeat intervals. The strategy to start screening at age 50 years and end screening at age 75 years with annual FIT testing provided the optimal strategy given about 1700 colonoscopies per 1000 individuals with 25 years of screening. Note that the strategies that start screening at older ages or with longer intervals before retesting are along the curve with fewer LYG but also fewer colonoscopies required. It is a societal choice as to what resources to commit to reach a given level of LYG.

(d) Additional cost–effectiveness considerations

(i) Strategies for limited budgets

Although RCTs are considered to be the reference standard for efficacy, it is not feasible to compare multiple strategies within an RCT setting (especially in a community setting). The microsimulation modelling groups can provide virtual trials that can explore many
more possible strategies based on the performance (sensitivity and specificity of advanced neoplasia) of FOBT from RCTs or observational studies. Other scenarios have also been explored with modelling for the best balance between LYG and resources in population screening. For example, in a setting where there is a limited budget that can cover only a fraction of the population, a programme of annual or biennial FIT for those aged 50–64 years would provide more LYG in a population setting compared with a one-time colonoscopy (van der Steen et al., 2015). If there is limited colonoscopy capacity to support screening, FIT could be used with a higher Hb cut-off level, to provide cost-effective strategies for a lower level of endoscopy service. However, FIT with a lower cut-off level of 10 μg Hb/g faeces is the most effective health outcome and cost compared with gFOBT (Wilschut et al., 2011).
(ii) **FOBT screening in the context of new treatments**

Lansdorp-Vogelaar et al. (2009) showed that as the costs for cancer care rise with increased use of newer and more expensive biological drugs, FOBT testing would be cost saving compared with no screening, because of preventing advanced cancers and deaths from CRC and avoiding costs of expensive biological drugs. Parekh et al. (2008) showed similar results.

(iii) **Hybrid strategies**

Early on in the development of CRC screening, Eddy (1990) suggested a hybrid strategy using sigmoidoscopy at 5-year intervals with FOBT annually, although this hybrid approach is not used very frequently in practice. More recently, Whyte et al. (2012) suggested starting with sigmoidoscopy at age 55 years and with biennial FIT at age 60 years as an effective and cost-effective strategy for the United Kingdom.

Dinh et al. (2013) suggested a screening strategy of annual or biennial FIT starting at age 50 years and a single colonoscopy at age 66 years as a favourable strategy for population screening. Knudsen et al. (2012) determined that those with a negative colonoscopy at age 50 years could be followed up with annual HsgFOBT or annual FIT with approximately the same benefit as rescreening at 10 years with colonoscopy.

3.3 Endoscopic methods

3.3.1 Techniques

(a) Introduction

The endoscopic methods for CRC screening use flexible cameras to directly visualize the rectum and colon. These techniques have five primary roles within the CRC screening process: (i) primary screening; (ii) follow-up of other abnormal screening tests (diagnosis); (iii) removal of precancerous lesions (prevention); (iv) removal of early cancers (treatment); and (v) long-term follow-up of patients who are at high risk because of previous neoplasms or increased individual risk (surveillance) (Tiro et al., 2014). Although these roles differ substantially in concept, they are similar with respect to equipment, expertise of personnel, quality control, screening performance, and the host factors that affect the examination. In this section, these concepts are summarized for the two main endoscopic techniques for CRC screening: sigmoidoscopy and colonoscopy.

(b) Endoscopic techniques for CRC screening

Sigmoidoscopy and colonoscopy are the two primary endoscopic techniques for CRC screening.

Sigmoidoscopy is the insertion of an endoscopic camera, typically flexible, for examination of the rectum and sigmoid colon; it can also potentially evaluate the descending colon, splenic flexure, and distal transverse colon. The process includes insertion of the scope into the anus, injection of air through the scope to expand the intestinal lumen and allow better visualization (also called insufflation), and passage of the scope to the desired extent of the examination. This is followed by gradual withdrawal of the scope. The examination of the intestinal lining for polyps and other abnormalities is performed both on insertion and on withdrawal, as is the washing and suctioning of any residual liquid. Because sigmoidoscopy is usually performed without sedation, the extent of the examination depends on patient comfort, bowel preparation, and instrument length (see Sections 3.3.1(d) and 3.3.1(f)). Sigmoidoscopy can remove smaller polyps and biopsy larger polyps; patients who are found to have precancerous polyps can be referred for colonoscopy.

The goal of colonoscopy is examination of the entire colon, from rectum to caecum. In many countries and settings, colonoscopy is commonly performed with sedation, which allows for instrument manipulation with greater patient comfort. Colonoscopy can remove small polyps and most large polyps; advanced techniques enable the removal of polyps up to several centimetres in size.

(c) Equipment and expertise of personnel

(i) Equipment

Gastrointestinal endoscopic procedures use flexible tubes with four main components: an imaging system, illumination devices, channels for passing instruments and performing suction, and mechanisms for adjusting the direction and performance characteristics of the tube (Konda et al., 2015). Scopes are provided by several different manufacturers; the primary differences are the imaging methods and the controls.

Imaging is provided through either small charge-coupled device-type camera chips or a fibre-optic bundle (Classen & Phillip, 1984). Camera chip-based units either directly detect or impute colours; these require a base unit for converting the electronic signals into images (Cho, 2015). In contrast, fibre-optic-based devices directly transmit images, although these are becoming less commonly used because of their lower optical resolution and fewer advanced imaging options compared with chip-based devices (Classen & Phillip, 1984; Cho, 2015). Numerous visualization methods have
been tested for enhancing polyp detection, such as narrow-band imaging and the use of dyes (chromoendoscopy), although none of them has convincingly increased the number of polyps detected in populations at average risk, independent of inspection time (Nagorni et al., 2012; Pasha et al., 2012; Omata et al., 2014; Bisschops et al., 2017). Several additional mechanical devices, scope designs (e.g. wide-angle viewing and multiple-screen images), and scope attachments for increasing visualization and polyp detection have been developed. Some of these may improve polyp detection; however, given their variety, an in-depth review of this topic is beyond the scope of this Handbook.

Illumination is provided by small light portals at the scope tip, using single or multiple sources; light sources can also be manipulated for image enhancement (Longcroft-Wheaton et al., 2012; Nagorni et al., 2012; Wallace et al., 2014). Some guidelines recommend high-definition white light endoscopes as the standard for screening, although the equipment version and imaging methods may vary by location. Continued improvements in imaging resolution are likely to further enhance screening performance. Single or multiple instrument channels within the scope allow the passage of forceps for biopsy, snares for polyp removal, devices for applying thermal current, and other tools.

(ii) Bowel preparation

A bowel preparation is needed before a sigmoidoscopy or a colonoscopy, to remove the stool and to enable adequate visualization of the colon. For bowel cleansing, it is recommended that patients have a low-residue or full-liquid diet on the day before the colonoscopy (Johnson et al., 2014); a clear liquid diet is not necessary and is associated with lower compliance.

Recommended bowel preparations before sigmoidoscopy include sodium phosphate enemas, often with an additional oral laxative, such as magnesium citrate. The combination of an oral agent and an enema is associated with a better preparation (Levin et al., 2005).

Numerous bowel preparations for colonoscopy exist, although the most effective ones include the patient receiving a dose within 4–6 hours of the colonoscopic examination (Johnson et al., 2014; Martel et al., 2015). The most common method currently used for colonoscopy is the split-dose preparation, such as with 4 litres of polyethylene glycol, in which the patient receives one half of the preparation the evening before the examination and the other half on the day of the examination. Patients who receive split-dose preparations are significantly more likely to have an adequate bowel preparation than those who receive day-before preparations (OR, 2.51; 95% CI, 1.86–3.39) (Martel et al., 2015). Patients also report being more willing to repeat a split-dose preparation than a single-dose day-before preparation. Same-day regimens may have equal effectiveness and can be considered for patients who undergo an examination in the afternoon (Johnson et al., 2014).

(iii) Expertise of personnel

Endoscopic training requires supervised education and proctoring (Adler et al., 2012; Sedlack et al., 2014). Substantial data exist on performance and training for both physician and non-physician endoscopists (Stephens et al., 2015). Competency standards have evolved from a minimum number of completed procedures to the documentation of a reliable ability to complete specific tasks (Sedlack et al., 2014; Rutter et al., 2016). Different skill levels are required for different procedures, and skill levels vary substantially. Sigmoidoscopies and colonoscopies can be completed within in-hospital settings, dedicated outpatient procedure units, and office-based settings; sigmoidoscopies, in particular, can be performed as high-volume activities. For CRC screening programmes in developed medical systems, it has been suggested that different levels of competency are required
for different procedures; at least level 1 competency is recommended to avoid otherwise unnecessary follow-up procedures to remove small polyps (Table 3.3.1) (Valori et al., 2012). Endoscopic examinations can be safely and effectively performed by both physician and non-physician endoscopists (Day et al., 2014). However, the lower direct costs of non-physician endoscopists may be offset by greater requirements for repeat examinations, specialty follow-up, and additional consultations (Stephens et al., 2015).

Requirements for endoscopy room personnel vary by the procedure performed, governmental regulations, and local practices (Dumonceau et al., 2013, 2015). At a minimum, the endoscopist should be assisted by one additional medical professional, typically a nurse or similarly certified member of personnel, responsible for patient monitoring and assisting with interruptible tasks such as biopsies. In some settings, a second assistant is routinely used, although guidelines suggest that this is required only if sustained additional technical assistance is required (Calderwood et al., 2014). Minimum competencies indicate that unlicensed personnel with sufficient initial and current training can assist with biopsies and similar procedures (Calderwood et al., 2014).

(iv) Infection control

Guidelines exist for endoscope processing, infection control, and administration of prophylactic antibiotics during procedures (Petersen et al., 2011; Jover et al., 2012; Hookey et al., 2013; Calderwood et al., 2014; SGNA Practice Committee 2013–14, 2015; Herrin et al., 2016; Son et al., 2017). These include recommendations for routine hand hygiene before patient contact; use of personal protective equipment, such as gloves, facial protection, and impervious gowns; administration of medication; and methods for handling potentially contaminated equipment (Petersen et al., 2011; Jover et al., 2012; Hookey et al., 2013; Calderwood et al., 2014; SGNA Practice Committee 2013–14, 2015; Herrin et al., 2016; Son et al., 2017).

(v) Sedation

Many colonoscopies and some sigmoidoscopies use conscious sedation according to patient preference, tolerance, and local practice (Bretthauer et al., 2016; Rees et al., 2016). Data on sedation are mainly for colonoscopies. Guidelines and training curricula exist for sedation and monitoring, although their evidence base is weak on whether routine compliance improves patient-related outcomes (Vargo et al., 2012; Dietrich et al., 2013; Calderwood et al., 2014); commonly used agents include midazolam, fentanyl, meperidine, and propofol (Dumonceau et al., 2015; Obara et al., 2015). Guidelines recommend pre-procedure evaluations of each patient’s physical status, such as with the criteria established by the American Society of Anesthesiologists; the Mallampati airway classification and risk factors for sedation; intraprocedural monitoring by qualified personnel of blood pressure, respiratory rate, heart rate, and pulse oximetry; availability of medication reversal agents; and post-procedure monitoring until the patient is stabilized (Calderwood et al., 2014).

(d) Technical quality control

Several performance standards and quality measures are recommended for lower gastrointestinal endoscopy (Minoli et al., 1999; Ball et al., 2004; Rex et al., 2006, 2015; Rembacken et al., 2012; Valori et al., 2012; Rutter et al., 2016; Kaminski et al., 2017a). A recent European guideline noted 44 different performance measures, many of which evaluate processes (e.g., documentation of certain findings) rather than evidence-based factors that influence outcomes (Rees et al., 2016). Additional recommendations exist for particular techniques, such as endoscopic polypectomy and endoscopic mucosal resection (Ferlitsch et al., 2017).
The three main measures of endoscopy quality that are clearly associated with patient outcomes are completion of the examination to the minimum desired extent, thoroughness of the endoscopic inspection, and adequacy of bowel preparation (see also Section 3.3.1(f))

The three main measures of endoscopy quality that are clearly associated with patient outcomes are completion of the examination to the minimum desired extent, thoroughness of the endoscopic inspection, and adequacy of bowel preparation (see also Section 3.3.1(f)) (Minoli et al., 1999; Ball et al., 2004; Rex et al., 2006, 2015; Rembacken et al., 2012; Valori et al., 2012; Rutter et al., 2016; Kaminski et al., 2017a). The minimum desired extent of the examination is the junction of the sigmoid and the descending colon for sigmoidoscopy (Atkin et al., 2002), and the caecum for colonoscopy. The actual proximal extent achieved for most sigmoidoscopies is not precisely defined, given the ambiguity of landmarks, and is often considered the maximum tolerated scope insertion distance, or approximately 60 cm of scope length (Painter et al., 1999; Weissfeld et al., 2000). The caecum is identified using the appendiceal orifice, ileocecal valve, and caecal sling fold (a combination of muscular folds around the appendix) (Rex et al., 2015).

The most validated measurement of the thoroughness of endoscopic inspection is the adenoma detection rate (ADR) of the physician. The physician ADR is the percentage of the physician’s examinations in which one or more adenomas are detected (Rex et al., 2006). Reported ADRs varied from less than 10% to more than 60% among reports from both academic and community-based colonoscopy providers (Hixson et al., 1990; Rex et al., 1997, 2006; Bretthauer et al., 2003; Hosokawa et al., 2003; Schoen et al., 2003; Atkin et al., 2004; Bressler et al., 2004; Leaper et al., 2004; Pickhardt et al., 2004; Sanchez et al., 2004; Barclay et al., 2006; Chen & Rex, 2007; Corley et al., 2011, 2014; Jensen et al., 2015) and from 8.6% to 15.9% for sigmoidoscopy in the United Kingdom Flexible Sigmoidoscopy Screening Trial (UKFSST) (Atkin et al., 2004). The prevalence of adenomas is higher with increasing patient age and is higher in men than in women, but no large differences in prevalence exist between racial or ethnic groups (Corley et al., 2013). Adjusting for differences in patient demographics only modestly influenced the overall variability in physician ADRs in a large community-based setting (Jensen et al.,...
Therefore, physician ADR appears to vary with physician-related factors during endoscopic inspection, rather than patient-related factors. Variation in physician ADR is strongly inversely associated with patients’ subsequent CRC outcomes for both colonoscopy and sigmoidoscopy. Studies in large populations in Europe and the USA demonstrated substantially lower future risks of post-colonoscopy CRC and death from CRC in patients of physicians with higher ADRs than in patients of those with lower ADRs (Kaminski et al., 2010; Rogal et al., 2013; Corley et al., 2014); a similar analysis for sigmoidoscopy demonstrated higher risks of post-sigmoidoscopy distal CRCs in patients of providers with lower ADRs. A community-based study demonstrated that each absolute increase of 1% in a physician’s ADR was associated with 3% and 5% decreases in their patients’ risks of future CRC (HR, 0.97; 95% CI, 0.96–0.98) and death from CRC (HR, 0.95; 95% CI, 0.94–0.97), respectively (Corley et al., 2014). A complementary modelling study estimated that lifetime risks of CRC incidence and mortality decreased by 11–13% for every 5% increase in ADR, translating to 53–60% lifetime differences between the lowest and the highest ADR quintiles (Meester et al., 2015). Variation in ADR could be associated with approximately one third of the total estimated mortality benefit from screening, compared with no screening (Meester et al., 2015). Improvements in ADR over time have also been associated with fewer deaths from CRC (Kaminski et al., 2017b). The physician ADR may have a comparably large influence on FIT-based screening programmes, because colonoscopy is required for follow-up after a positive FIT result. In response to these collective findings, minimum target ADRs recommended in quality guidelines for screening colonoscopy were recently increased to 25% (or from 15% to 20% for women and from 25% to 30% for men) (Rex et al., 2015), and ADR was adopted by the United States Centers for Medicare & Medicaid Services as a quality measure (Centers for Medicare & Medicaid Services, 2017). The polyp detection rate can be a surrogate for ADR if pathology data are not readily available (Williams et al., 2012; Patel et al., 2013). Fewer data exist on ADR guidelines for sigmoidoscopy; the United Kingdom Joint Advisory Group recommends a minimum ADR of 10% for sigmoidoscopy (Valori & Barton, 2007). The relative paucity of recommendations for sigmoidoscopy is partly due to the fact that sigmoidoscopy has a less standardized extent of examination, which influences polyp detection rate (Segnan et al., 2007; Fracchia et al., 2010). Cumulatively, these findings and recommendations indicate that measures to increase ADR at either the patient level (e.g. adequate bowel preparation) or the provider level are appropriate targets for ADR interventions for both sigmoidoscopy and colonoscopy providers.

Incomplete resection of precancerous polyps is also likely to influence patients’ risk of post-colonoscopy CRC, although it is difficult to calculate the effect magnitude versus such cancers arising from undetected or new polyps (Erichsen et al., 2013; Pohl et al., 2013; Samadder et al., 2014; Pullens et al., 2015). In one recent study, approximately one third of post-colonoscopy cancers were in the same colorectal segment (e.g. ascending colon or transverse colon) as a previously resected adenoma (Belderbos et al., 2017). To decrease the risk of incomplete removal, a guideline recommends snare removal (instead of biopsy forceps) for polyps larger than 3 mm, although the recommendation’s evidence base is modest, particularly for relatively small polyps such as those 4–6 mm in size (Lee et al., 2013; Kim et al., 2015).

Although this was not explicitly stated by the guidelines, many of the listed metric methods are readily adaptable to measuring the quality of sigmoidoscopy, but few data are available to support metrics for sigmoidoscopy (Fig. 3.3.1). Performance guidelines for sigmoidoscopy focus primarily on technical skills, such as threshold limit of complications (Rees et al., 2016) and

Data from the European working group (Valori et al., 2012; Kaminski et al., 2017a), United States (Levin et al., 2005), and United Kingdom guidelines (Rees et al., 2016), and with reference scales/metrics for bowel preparation (Aronchick et al., 1999; Rostom & Jolicoeur, 2004), procedure indication (American Society for Gastrointestinal Endoscopy, 2000; Juillerat et al., 2009), and patient experience (Breivik et al., 2000; Skovlund et al., 2005).
Colorectal cancer screening

(e) Performance of screening endoscopy

The goals of screening are to detect CRC (early detection) and to remove precancerous polyps (cancer prevention). Therefore, the performance of screening endoscopy is the ability of the examination to detect CRC and to remove precancerous polyps.

The performance of sigmoidoscopy, particularly for proximal colon cancer, depends in part on the threshold for referral to colonoscopy, as regards polyp characteristics. Colonoscopy referral criteria used by some recent RCTs included (i) any polyp or mass (Prostate, Lung, Colorectal, and Ovarian [PLCO] Cancer Screening Trial in the USA; biopsies not routinely performed); (ii) any CRC, polyp > 5 mm in diameter, ≥ 3 adenomas, or any adenoma with high-grade dysplasia or villous histology (Screening for Colon and Rectum [SCORE] trial in Italy); (iii) any CRC, any adenoma, or any polyp > 10 mm (Norwegian Colorectal Cancer Prevention [NORCCAP] trial); and (iv) any CRC, any polyp > 10 mm, any polyp with tubulovillous or villous histology, or ≥ 3 adenomas (UKFSST) (Castells et al., 2013; Holme et al., 2017). A comparison of the latter three strategies suggested that for the goal of detecting an advanced adenoma or an invasive cancer of the proximal colon with colonoscopy, the NORCCAP trial criteria provided the greatest sensitivity, whereas the UKFSST criteria provided the lowest number of people needed to refer to colonoscopy per advanced proximal neoplasm detected (Castells et al., 2013).

Comprehensive summaries estimated that the sensitivity of endoscopy, within the examined segments, was approximately 95% for the detection of CRC; these estimates are derived mainly from tandem colonoscopy studies, in which a patient underwent two examinations. The estimated sensitivity of endoscopy for the detection of adenomas varied by polyp size: 95% for adenomas ≥ 10 mm, 85% for adenomas of 6–9 mm, and 75% for adenomas of 1–5 mm (van Rijn et al., 2006). The sensitivity of colonoscopy for the detection of proximal colorectal polyps may be somewhat lower, although the absence of a reference standard for identifying difficult-to-see sessile lesions complicates these sensitivity calculations. An RCT of a standard inspection of the proximal colon followed by either an additional inspection in retroflexion or a second forward-view examination demonstrated overall ADRs of 47% and 47%, respectively, and found that at least one additional adenoma was detected on second withdrawal in similar proportions (7.5% with retroflex and 10.5% with repeat forward view) (Kushnir et al., 2015). Sigmoidoscopy has similar assumed performance characteristics for lesions within reach of the examination (e.g. within 50 cm) (Knudsen et al., 2016).

Direct comparisons of the yields of sigmoidoscopy and colonoscopy are difficult, given that the typical sigmoidoscopy can inspect from the rectum up to the mid-sigmoid colon or, less commonly, the distal transverse colon. A multicentre colonoscopy trial estimated that of 3121 people who underwent a colonoscopy, 37.5% had ≥ 1 neoplastic lesion anywhere in the colon, and 329 (10.5%) had an advanced neoplasia/adenoma (≥ 10 mm, villous histology, high-grade dysplasia, or cancer). Of the 329 patients with an advanced neoplasia, in 128 it was proximal to the splenic flexure (the typical maximum extent of a sigmoidoscopy) and in 228 it was distal to the splenic flexure. The likelihood that the advanced proximal neoplasia would have been detected if the patients were initially screened with sigmoidoscopy was estimated, using the assumption that a full colonoscopy would be performed for...
any distal colon adenoma. Of the patients with an advanced proximal neoplasia, 48.4% (62 of 128) had ≥ 1 distal colon adenoma (Lieberman et al., 2000). Therefore, a sigmoidoscopy screening strategy would presumably detect a large majority of distal advanced adenomas and, when a distal advanced adenoma is detected, lead to a colonoscopic examination of the proximal colon. However, these results may be due to the fact that most of the study population in the trial were men (n = 3021), in whom the prevalence of advanced adenoma and invasive cancer of the colon and the rectum was higher than that in adults at average risk (Heitman et al., 2009). The relative effects of sigmoidoscopy versus colonoscopy on small adenomas and sessile adenomas were less clear.

The ability of sigmoidoscopy and colonoscopy to distinguish between cancerous and non-cancerous lesions depends largely on pathology, which has moderate interobserver variability for villous, dysplastic (Costantini et al., 2003; Mahajan et al., 2013; Osmond et al., 2014), and malignant features, and for identifying serrated polyps and adenomas versus non-adenomas (Turner et al., 2013; Schachschal et al., 2016); interobserver variability includes differences between pathologists within the same country and differences in interpretation between countries (Schlemper et al., 1998). Classification methods based solely on the endoscopic appearance of polyps have been proposed to enable more selective pathological confirmation, but these are currently not widely used.

(f) Host factors that affect screening performance

The primary host factors that influence screening performance are the patient’s ability to complete the examination and the quality of the bowel preparation. Patient factors associated with inadequate bowel cleansing include a history of constipation, inability to complete the bowel preparation (primarily because of nausea), and use of neuroleptic or antidepressant medications (Hautefeuille et al., 2014). Other factors related to incomplete sigmoidoscopy and colonoscopy include older patient age, female sex, and previous abdominal or pelvic surgery (Ramakrishnan & Scheid, 2003; Shah et al., 2007; Laiyemo et al., 2012).

Bowel preparation is central to screening performance for both sigmoidoscopy and colonoscopy. For colonoscopy, adenoma detection is substantially reduced among patients with inadequate bowel preparations, for both non-advanced adenomas (OR, 0.53; 95% CI, 0.46–0.62) and advanced adenomas (OR, 0.74; 95% CI, 0.62–0.87) (Sulz et al., 2016). However, bowel preparation represents a continuum, and how different levels of preparation influence adenoma detection is less certain. A recent data synthesis of different levels of bowel preparation found, when comparing low-, intermediate-, and high-quality bowel preparations, an absolute increase of 5% in colonoscopy ADRs for both intermediate- and high-quality preparations, compared with low-quality preparation (OR, 1.39; 95% CI, 1.08–1.79 for intermediate quality; OR, 1.41; 95% CI, 1.21–1.64 for high quality), but no large differences were found between intermediate- and high-quality preparations (Clark et al., 2014). Therefore, for patients who undergo routine screening or surveillance examinations with “inadequate” preparations, it is recommended that the examination should be repeated within 1 year (Johnson et al., 2014).

Patient education may improve the quality of the bowel preparation. A meta-analysis of RCTs of patient education measures suggested that a brief information or counselling session significantly improved the adequacy of bowel preparation (RR, 1.22; 95% CI, 1.10–1.36), with a marginal trend towards decreasing the likelihood of needing a repeat colonoscopy (RR, 0.52, CI, 0.25–1.04) (Chang et al., 2015). Similar findings were noted for a greater likelihood of an adequate bowel preparation among those receiving “enhanced” instructions, consisting
of both verbal and written information, versus written information alone (OR, 2.35; 95% CI, 1.65–3.35) (Guo et al., 2017).

### 3.3.2 Randomized controlled trials

(a) **RCTs of sigmoidoscopy**

Four RCTs of sigmoidoscopy with CRC mortality and/or CRC incidence as end-points have been published. Note that this excludes one very small trial with 799 total subjects randomized (Thiis-Evensen et al., 1999a). Table 3.3.2, Table 3.3.3, Table 3.3.4, and Table 3.3.5 describe the design and findings of the four RCTs.

(b) **Descriptions of RCTs**

(i) **PLCO trial**

The PLCO trial in the USA examined screening for four different cancers (Schoen et al., 2012). In 1993–2001 at 10 screening centres, subjects aged 55–74 years were individually randomized to either an intervention arm or a usual-care arm. All subjects provided informed consent, with consent generally before randomization. Subjects in the intervention arm were offered screening for CRC, lung cancer, and either prostate cancer (men) or ovarian cancer (women). For the CRC screening component, subjects were offered sigmoidoscopy at baseline and either at 3 years (for those who were randomized before April 1995) or at 5 years. A positive sigmoidoscopy screening result was defined as the detection of a polyp or mass. Subjects with a positive screening result were referred to their health-care providers for follow-up; the PLCO trial did not dictate or perform follow-up. By trial protocol, polyps were not removed at the screening sigmoidoscopy. Subjects with adenomas (or CRC) detected on follow-up endoscopy after a positive screening result were advised not to return for the subsequent screening; they received surveillance colonoscopy in accordance with community standards.

Exclusion criteria for the PLCO trial included a history of prostate cancer, lung cancer, ovarian cancer, or CRC and current treatment for cancer. Starting in April 1995, subjects who had undergone a colonoscopy or sigmoidoscopy in the previous 3 years were also ineligible for the trial.

The primary outcome of the CRC screening component was CRC-specific mortality, with CRC incidence as a secondary outcome. Planned follow-up was for 13 years or until 31 December 2009, whichever came first.

A total of 77 445 individuals were randomized to the intervention arm and 77 455 to the usual-care arm; 50.5% of the subjects in each arm were women. In the intervention arm, 83.5% of subjects received the baseline sigmoidoscopy screen and 54.0% received the second-round screen; 86.6% of subjects received at least one sigmoidoscopy screen. The rates of positive screening results were 23.4% at the baseline screen and 23.5% at the subsequent screen. Of those with a positive screening result, 80.5% received some diagnostic follow-up within 1 year, of whom 95.6% received colonoscopy. Of all subjects in the intervention arm, 21.9% received a colonoscopy follow-up of a positive sigmoidoscopy screening result.

The use of sigmoidoscopy and colonoscopy in the usual-care arm was monitored on a sampling basis. The estimated rates of endoscopic examination during the screening phase of the trial (the first 6 years of the study) were 25.8% for sigmoidoscopy, 34.4% for colonoscopy, and 46.5% for either sigmoidoscopy or colonoscopy. An ancillary study was performed to examine the use of surveillance colonoscopy in subjects in the intervention arm who had a positive baseline screening result and had adenomas removed on the subsequent colonoscopy. After a median follow-up of 8.9 years, 79.3% of subjects with advanced adenomas, 81.9% of subjects with ≥ 3 non-advanced adenomas, and 74.2% of subjects with 1 or 2 non-advanced adenomas had received at least one post-baseline colonoscopy.
(ii) UKFSST

The UKFSST was an RCT of once-only screening with sigmoidoscopy (*Atkin et al.*, 2010). Men and women aged 55–64 years who were registered with participating general practices in the United Kingdom were eligible for the trial, provided they had no history of CRC, adenomas, or inflammatory bowel disease, had a life expectancy of at least 5 years, and had not received a colonoscopy or sigmoidoscopy in the previous 3 years. Eligible subjects (368,142) were first sent a questionnaire asking whether they would participate in an RCT of CRC screening. Those who agreed to participate were then randomized in a 2:1 ratio to the control arm or the intervention arm of the trial.

Subjects in the intervention arm underwent baseline sigmoidoscopy with polypectomy. Those with polyps meeting any of the following criteria were referred for colonoscopy: ≥ 10 mm in diameter, ≥ 3 adenomas, tubulovillous or villous histology, high-grade dysplasia, malignancy, or ≥ 20 hyperplastic polyps above the distal rectum.

Trial enrolment began in November 1994 and was completed in March 1999. A total of 170,432 individuals were randomized, and after exclusions for deaths and previous CRC, 170,038 were included in the analysis (112,939 in the control arm and 57,099 in the intervention arm); 50.0% were women. The participation rate in the baseline screening was 71%; of those screened, 5% underwent follow-up colonoscopy, of whom 85% subsequently entered a surveillance programme.

(iii) NORCCAP trial

The NORCCAP trial was an RCT of once-only screening with sigmoidoscopy (*Holme et al.*, 2014). Men and women aged 55–64 years living in the city of Oslo or in Telemark County, Norway, were identified through population registers. In 1998, birth cohorts were randomly sampled to be invited to the screening arm or included in the control arm; subjects in the control arm were not contacted. In 2000, the trial was extended to include individuals aged 50–54 years. The ratios of subjects aged 55–64 years to those aged 50–54 years differed between the screening arm and the control arm; subjects in the control arm were younger than those in the screening arm. Subjects in the screening arm were further randomized in a 1:1 ratio to receive either

CI, confidence interval; HR, hazard ratio; NORCCAP, Norwegian Colorectal Cancer Prevention trial; PLCO, Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial; RR, relative risk; SCORE, Screening for Colon and Rectum trial; UKFSST, United Kingdom Flexible Sigmoidoscopy Screening Trial.

* Based on initial report; median follow-up, 11.2 years.

b Based on extended follow-up analysis; median follow-up, 17.1 years.
sigmoidoscopy plus FIT at baseline or only a baseline sigmoidoscopy. All visible lesions were removed at sigmoidoscopy and subjected to histopathology; subjects with a polyp ≥ 10 mm, any adenoma or suspected CRC, or a positive FIT result were referred for colonoscopy, at which time all polyps were removed.

A total of 20,780 subjects were randomized to the screening arm and 79,430 to the control arm. After exclusions for deaths and previous CRC, 20,572 subjects were analysed in the screening arm and 78,220 in the control arm; 50.1% were women. The participation rate for screening sigmoidoscopy was 63.0%; of those screened, 19.5% attended follow-up colonoscopy and 9.8% were recommended for surveillance colonoscopy.

(iv) SCORE trial

The SCORE trial in Italy was an RCT of once-only screening with sigmoidoscopy (Segnan et al., 2002). Ineligibility criteria included a personal history of CRC, adenoma, or inflammatory bowel disease, having undergone a lower gastrointestinal endoscopy in the previous 2 years, having two or more first-degree relatives with CRC, or having a medical condition that precluded a benefit from screening. Individuals aged 55–64 years who responded to a mailed questionnaire that they certainly or probably would attend screening if offered were randomized to an intervention arm (17,148) or a control arm (17,144); 50.0% were women. In three centres (Biella, Genoa, and Milan), with 16,690 subjects, randomization was at the individual level; in the three other centres (Arezzo, Rimini, and Turin), with 17,602 subjects, cluster randomization was used, and the unit of randomization was the general practitioner. Subjects in the control arm were not contacted further. The data set for the final analysis excluded 12 subjects in the intervention arm and 8 subjects in the control arm, because of death or CRC diagnosis before randomization; therefore, it included 17,136 subjects in each arm.

Diminutive polyps (≤ 5 mm) were removed at sigmoidoscopy. Subjects with larger polyps (> 5 mm), 3 or more adenomas, adenomas with more than 20% villous component, severe dysplasia, or CRC and subjects with inadequate bowel preparation and at least one polyp were referred for colonoscopy.

Of the 17,148 individuals in the screening arm, 9999 (58.3%) attended the screening and 9911 (57.8%) were actually screened (the remaining 88 were referred for later screening because of inadequate bowel preparation but did not return for screening). After screening,
20 (0.2%) were immediately referred to surgery and 775 (8%) attended colonoscopy. Subsequent surveillance colonoscopy was indicated for 395 subjects.

(c) Effects on CRC incidence and mortality and all-cause mortality

This section summarizes findings from the RCTs on the effects of sigmoidoscopy on CRC mortality, CRC incidence, and all-cause mortality. All relative risks and hazard ratios are from intention-to-treat analyses, unless otherwise stated. For per-protocol analyses, the UKFSST and the SCORE trial reported adjusted relative risks derived using the Cuzick method (Cuzick et al., 1997). The NORCCAP trial reported per-protocol 10-year risk differences using an instrumental variable approach; these were converted to relative risks to obtain a comparable metric to that reported for the other trials. The PLCO trial did not report per-protocol analyses.

[For the SCORE trial, in the statistical methods section of the final outcome publication (Segnan et al., 2011), there is no indication that the statistical analysis took into account the cluster randomization of the three centres; the computed 95% confidence intervals seem to have been calculated from only person-years and the number of reported events.]

(i) CRC mortality

In the PLCO trial, after a median follow-up of 12.1 years, the relative risk of CRC-specific mortality was 0.74 (95% CI, 0.63–0.87) (Schoen et al., 2012). The relative risk was 0.50 (95% CI, 0.38–0.64) for distal CRC and 0.97 (95% CI, 0.77–1.22) for proximal CRC. Stratified analyses showed that the relative risk of CRC-specific mortality was 0.84 (95% CI, 0.67–1.06) for those aged 55–64 years and 0.65 (95% CI, 0.52–0.82) for those aged 65–74 years ($P_{interaction} = 0.11$). By sex, the relative risk was 0.66 (95% CI, 0.53–0.81) for men and 0.87 (95% CI, 0.68–1.12) for women ($P_{interaction} = 0.10$).

In the UKFSST, an initial analysis of the primary end-points, published in 2010, with a median follow-up of 11.2 years, showed a hazard ratio for CRC mortality of 0.69 (95% CI, 0.59–0.82) (Atkin et al., 2010). By anatomical location, the mortality rate ratio was 0.58 (95% CI, 0.46–0.74) for distal CRC and 0.87 (95% CI, 0.68–1.12) for proximal CRC (Lin et al., 2016b). An extended follow-up analysis was published in 2017, with a median follow-up of 17.1 years (Atkin et al., 2017). The hazard ratio for CRC mortality was 0.70 (95% CI, 0.62–0.79). The hazard ratio for CRC mortality was also reported by anatomical location: 0.54 (95% CI, 0.45–0.65) for distal CRC and 0.91 (95% CI, 0.76–1.08) for proximal CRC. The hazard ratio for CRC mortality (in the extended follow-up analysis) by age was 0.67 (95% CI, 0.55–0.81) for those aged 55–59 years and 0.72 (95% CI, 0.62–0.84) for those aged 60–64 years ($P_{interaction} = 0.519$). By sex, the hazard ratio was 0.67 (95% CI, 0.57–0.79) for men and 0.74 (95% CI, 0.61–0.90) for women ($P_{interaction} = 0.417$). In the per-protocol analysis (extended follow-up), the relative risk was 0.59 (95% CI, 0.49–0.70) for overall CRC mortality and 0.34 (95% CI, 0.26–0.46) for distal CRC mortality.

In the NORCCAP trial, the (age-adjusted) hazard ratio for CRC mortality was 0.73 (95% CI, 0.56–0.94) (Holme et al., 2014). The hazard ratio was 0.79 (95% CI, 0.55–1.11) for distal CRC mortality and 0.73 (95% CI, 0.49–1.09) for proximal CRC mortality. The hazard ratio for mortality did not differ significantly by subgroup of the screening arm; the hazard ratio was 0.62 for sigmoidoscopy plus FOBT and 0.84 for sigmoidoscopy alone ($P_{heterogeneity} = 0.20$). By age group, the hazard ratios were similar for those aged 50–54 years (HR, 0.74; 95% CI, 0.40–1.35) and those aged 55–64 years (HR, 0.73; 95% CI, 0.55–0.97). By sex, the hazard ratio was 0.58 (95% CI, 0.40–0.85) for men and 0.91 (95% CI, 0.64–1.30) for women ($P_{interaction} = 0.10$). In
In the SCORE trial, the median follow-up was 11.4 years for CRC mortality (Segnan et al., 2011). The relative risk of CRC mortality was 0.78 (95% CI, 0.56–1.08). The relative risk was 0.73 (95% CI, 0.47–1.12) for distal CRC and 0.85 (95% CI, 0.52–1.39) for proximal CRC. In the per-protocol analysis, the relative risk was 0.62 (95% CI, 0.40–0.96) for overall CRC mortality and 0.48 (95% CI, 0.24–0.94) for distal CRC mortality.

(ii) **CRC incidence**

In the PLCO trial, the relative risk of CRC incidence was 0.79 (95% CI, 0.72–0.85) (Schoen et al., 2012). The relative risk was 0.71 (95% CI, 0.64–0.80) for distal CRC incidence and 0.86 (95% CI, 0.76–0.97) for proximal CRC incidence. The relative risk of CRC incidence was similar by age: 0.78 (95% CI, 0.69–0.87) for those aged 55–64 years and 0.79 (95% CI, 0.71–0.89) for those aged 65–74 years. By sex, the relative risk was 0.73 (95% CI, 0.66–0.82) for men and 0.86 (95% CI, 0.76–0.98) for women, indicating a borderline significant interaction ($P_{interaction} = 0.052$).

In the UKFSST, the hazard ratio for CRC incidence was 0.77 (95% CI, 0.70–0.84) in the earlier analysis (Atkin et al., 2010). The hazard ratio was 0.64 (95% CI, 0.57–0.72) for distal CRC incidence and 0.98 (95% CI, 0.85–1.12) for proximal CRC incidence (Lin et al., 2016b). In the extended follow-up analysis, the hazard ratio for CRC incidence was 0.74 (95% CI, 0.70–0.80); the hazard ratio was 0.59 (95% CI, 0.54–0.64) for distal CRC incidence and 0.96 (95% CI, 0.87–1.06) proximal CRC incidence (Atkin et al., 2017); the hazard ratios for CRC incidence were similar for those aged 55–59 years (HR, 0.74; 95% CI, 0.67–0.82) and those aged 60–64 years (HR, 0.75; 95% CI, 0.69–0.82). By sex, the hazard ratio was 0.70 (95% CI, 0.65–0.77) for men and 0.81 (95% CI, 0.73–0.89) for women ($P_{interaction} = 0.047$). In the per-protocol analysis (extended follow-up), the relative risk was 0.65 (95% CI, 0.59–0.71) for overall CRC incidence and 0.44 (95% CI, 0.38–0.50) for distal CRC incidence.

In the NORCCAP trial, the median follow-up was 11.2 years in the screening arm and 10.9 years in the control arm (Holme et al., 2014). The (age-adjusted) hazard ratio for CRC incidence was 0.80 (95% CI, 0.70–0.92). The hazard ratio was 0.76 (95% CI, 0.63–0.92) for distal CRC incidence and 0.90 (95% CI, 0.73–1.10) for proximal CRC incidence. The hazard ratio for CRC incidence did not differ significantly by subgroup of the screening arm; the hazard ratio was 0.88 for sigmoidoscopy plus FIT and 0.72 for sigmoidoscopy alone ($P_{heterogeneity} = 0.11$). By age group, the hazard ratio for CRC incidence was 0.68 (95% CI, 0.49–0.94) for those aged 50–54 years and 0.83 (95% CI, 0.71–0.96) for those aged 55–64 years ($P_{interaction} = 0.27$). By sex, the hazard ratio was 0.73 (95% CI, 0.60–0.89) for men and 0.87 (95% CI, 0.72–1.06) for women ($P_{interaction} = 0.26$). In the per-protocol analysis, the relative risk of CRC incidence was 0.68 (95% CI, 0.56–0.86). [After the Working Group meeting, updated results (with a median follow-up of 14.8 years) were reported (Holme et al., 2018).]

In the SCORE trial, the median follow-up was 10.5 years for CRC incidence (Segnan et al., 2011). The relative risk of CRC incidence was 0.82 (95% CI, 0.69–0.96). The relative risk was 0.76 (95% CI, 0.62–0.94) for distal CRC incidence and 0.91 (95% CI, 0.69–1.20) for proximal CRC incidence. By age group, the relative risk was 0.84 (95% CI, 0.67–1.06) for those aged 55–59 years and 0.79 (95% CI, 0.62–1.00) for those aged 60–64 years. By sex, the relative risk was 0.88 (95% CI, 0.71–1.09) for men and 0.72 (95% CI, 0.55–0.96) for women. In the per-protocol analysis, the relative risk was 0.69 (95% CI, 0.56–0.86) for overall CRC incidence and 0.60 (95% CI, 0.46–0.80) for distal CRC incidence.
(iii) All-cause mortality

In the UKFSST, the hazard ratio for all-cause mortality was 0.97 (95% CI, 0.94–1.00) in the earlier analysis and 0.99 (95% CI, 0.97–1.01) in the extended follow-up analysis (Atkin et al., 2010, 2017).

In the NORCCAP trial, the relative risk of all-cause mortality was 0.97 (95% CI, 0.93–1.02) (Holme et al., 2014).

In the SCORE trial, all-cause mortality rates were reported as 660.26 per 100 000 person-years in the control arm and 640.96 per 100 000 person-years in the intervention arm, based on 1233 deaths in the control arm and 1202 deaths in the intervention arm (Segnan et al., 2011). [From these mortality rates and numbers of deaths, the relative risk is 0.75 (95% CI, 0.55–1.02).]

In the PLCO trial, the numbers of deaths from all causes excluding cancers of the colorectum, prostate, ovary, and lung were reported as 9138 in the intervention arm and 9286 in the control arm (Schoen et al., 2012). [Using the number of deaths from CRC (252 in the intervention arm and 341 in the control arm) and the total person-years for mortality, the relative risk of mortality from all causes excluding cancers of the lung, ovary, and prostate is 0.98 (95% CI, 0.95–1.01).]

(iv) Meta-analyses and pooled analyses of RCTs of sigmoidoscopy

Several meta-analyses of RCTs of sigmoidoscopy have been performed using the results from the four RCTs described above (PLCO, UKFSST, NORCCAP, and SCORE) (Fitzpatrick-Lewis et al., 2016; Lin et al., 2016a, b; Tinmouth et al., 2016). None of these included the updated findings of the UKFSST. Another meta-analysis, performed as a Cochrane systematic review (Holme et al., 2013), included only preliminary findings from the NORCCAP trial, with 7 years of follow-up, compared with the 11 years of follow-up used in the later NORCCAP publication; therefore, quantitative estimates from that meta-analysis are not included here. However, the trial ratings from Holme et al. (2013), as well as those from Lin et al. (2016a), are summarized below.

The Cochrane review (Holme et al., 2013) examined six potential factors related to risk of bias in the trials: random sequence generation (selection bias), allocation concealment (selection bias), blinding (performance bias and detection bias), incomplete outcome data (attrition bias), selective reporting (reporting bias), and other bias. For three of the four RCTs (UKFSST, NORCCAP, and SCORE), the risk of bias was rated as low for all factors; for the PLCO trial, the risk of bias was rated as low for all factors except selective reporting, which was rated as unclear risk. Lin et al. (2016a) evaluated each trial for overall quality using criteria developed by the USPSTF. All four trials were rated as of fair quality.

The meta-analyses differed quantitatively with respect to several minor factors (Table 3.3.6). In addition, two (Fitzpatrick-Lewis et al., 2016; Lin et al., 2016b) of the three analyses did not adjust for age in the NORCCAP trial (i.e. they used the unadjusted instead of the adjusted relative risks). This had a relatively small effect on the final relative risk estimates for CRC incidence and mortality but a larger relative effect on all-cause mortality. [Because subjects in the screening arm were (by design) older than subjects in the control arm in the NORCCAP trial, not adjusting for age in the NORCCAP trial in a meta-analysis severely biased the overall relative risk estimate against finding an overall mortality reduction in the screening arm versus the control arm. Therefore, the results for all-cause mortality in the meta-analyses that did not adjust for age in the NORCCAP trial are not valid.]

For CRC mortality, the results for the three meta-analyses were similar, with combined relative risk estimates ranging from 0.72 (95% CI, 0.65–0.80) to 0.74 (95% CI, 0.67–0.83). Two of the meta-analyses (Lin et al., 2016b; Tinmouth et al., 2016) examined CRC incidence, with combined

CI, confidence interval; CRC, colorectal cancer; NORCCAP, Norwegian Colorectal Cancer Prevention trial; PLCO, Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial; PYs, person-years; RR, relative risk; SCORE, Screening for Colon and Rectum trial; UKFSST, United Kingdom Flexible Sigmoidoscopy Screening Trial.

a Trials included were PLCO, UKFSST, NORCCAP, and SCORE.
b Did not adjust for age in the NORCCAP trial.
c Excluded the sigmoidoscopy plus FIT subgroup in the NORCCAP trial.
d For PLCO, deaths from lung, ovarian, and prostate cancers were not reported; Lin et al. excluded the PLCO trial for this reason.
relative risk estimates of 0.79 (95% CI, 0.75–0.85) and 0.78 (95% CI, 0.74–0.83), respectively. With respect to all-cause mortality, the one meta-analysis that adjusted for age in the NORCCAP trial (Tinmouth et al., 2016) found a significant reduction with sigmoidoscopy in all-cause mortality, with a relative risk of 0.97 (95% CI, 0.96–0.99) (Table 3.3.6).

A pooled analysis of the PLCO, NORCCAP, and SCORE trials estimated the relative risk of CRC incidence and mortality in men and women (Holme et al., 2017). For CRC incidence, the relative risks were 0.76 (95% CI, 0.70–0.83) for men and 0.83 (95% CI, 0.75–0.92) for women. No difference in the effect of screening was seen between men younger than 60 years and those aged 60 years or older. In contrast, screening reduced the incidence of CRC in women younger than 60 years (RR, 0.71; 95% CI, 0.59–0.84) but not significantly in those aged 60 years or older (RR, 0.90; 95% CI, 0.80–1.02). For CRC mortality, the relative risks were 0.67 (95% CI, 0.57–0.80) for men and 0.82 (95% CI, 0.67–1.00) for women. Screening reduced CRC mortality significantly in both younger and older men as well as in women younger than 60 years.

(d) Colonoscopy

There are currently four trials under way of screening colonoscopy versus FIT and/or no screening: one in Spain; one in Sweden; one in the Netherlands, Norway, and Poland; and one in the USA (Robertson et al., 2015). To date, there are no reported results on CRC incidence or mortality from these trials.

3.3.3 Observational studies on preventive effects of endoscopy

The observational studies that fulfilled the two Working Group criteria (see Section 3.1) and were included in the cited systematic review (Brenner et al., 2014a) and/or found separately in the literature search are described in detail under cohort and case–control studies below.

(a) Sigmoidoscopy

(i) Meta-analyses

The most recent systematic review of observational studies of endoscopy (Brenner et al., 2014a) included a total of two cohort studies and seven case–control studies (published in 1992–2013) in a meta-analysis of the effectiveness of sigmoidoscopy screening. [All nine studies met the Working Group criteria except Nishihara et al. (2013), which excluded prevalent cancers at baseline (the study is reported in the tables because it is included in the meta-analysis of mortality, but it is otherwise not highlighted in the text). There was heterogeneity among the included studies, for example in the designs, in the study populations (seven in the USA, one in Canada, and one in Sweden), and in adjustment for confounders (from only sex and age up to 16 variables) in the analyses, potentially biasing the effectiveness and maximum time frames of sigmoidoscopy before CRC diagnosis or mortality from 8–25 years.] The included studies are presented in Table 3.3.7 and Table 3.3.8.

The estimated meta-risk reduction for CRC incidence (five studies) was 49% (RR, 0.51; 95% CI, 0.39–0.65), with an incidence reduction of 64% (RR, 0.36; 95% CI, 0.26–0.50) for distal CRC, compared with 24% (RR, 0.76; 95% CI, 0.65–0.90) for proximal CRC. Mortality reduction was evaluated by pooling the results from four studies including Nishihara et al. (2013). The estimated overall risk reduction for CRC mortality was 47% (RR, 0.53; 95% CI, 0.30–0.97), with a mortality reduction of 66% (RR, 0.34; 95% CI, 0.19–0.62) for distal CRC, but with no mortality reduction for proximal CRC (RR, 0.96; 95% CI, 0.74–1.23). The heterogeneity in the meta-analysis of distal CRC mortality (and overall CRC mortality) was mostly caused by the large risk reduction (79%) demonstrated in the small case–control study.

* Included in meta-analyses of CRC incidence and mortality reduction of sigmoidoscopy by Brenner et al. (2014a).

* Of all screening modalities evaluated, not sigmoidoscopy specifically.
Colorectal cancer screening

by Newcomb et al. (1992); when that study was excluded, the mortality reduction was 63% for distal CRC (compared with 66% reported earlier) and 35% for overall CRC mortality (compared with 47% reported earlier).

(ii) Cohort studies

There were only two cohort studies performed in a screening setting: the study by Nishihara et al. (2013), which did not fulfil the inclusion criteria because it excluded prevalent cancers at baseline and only reported outcome measures after a negative endoscopy, and a smaller study by Blom et al. (2008) (Table 3.3.7). The study by Blom et al. (2008) was a prospective pilot study of screening sigmoidoscopy in the population at average risk. Approximately 2000 individuals aged 59–61 years were randomly selected and invited for a sigmoidoscopy examination. During follow-up, only 5 CRCs were diagnosed among participants and 16 among non-participants; the reduction in incidence was a non-significant 50%.

(iii) Case–control studies

With respect to the effect of screening sigmoidoscopy on CRC incidence, four case–control studies have been performed, all in North America (Table 3.3.8). In three of the studies (Slattery et al., 2000; Newcomb et al., 2003; Cotterchio et al., 2005), the participants were asked to report – in questionnaires or interviews – background factors and any screening examination (check-up). [The use of questionnaires adds recall bias to the bias of self-selection to screening. Another limitation of the generalizability of the three studies is that the CRC cases and controls had a wide range of ages, including relatively young individuals who did not represent an eligible screening population at average risk.]

Slattery et al. (2000) stratified by sex and demonstrated a reduction in overall CRC incidence of 40% (OR, 0.6; 95% CI, 0.4–0.8) in men and 50% (OR, 0.5; 95% CI, 0.3–0.8) in women. There was a significant reduction in incidence in men for distal CRC (OR, 0.5; 95% CI, 0.3–0.7) but not for proximal CRC (OR, 0.7; 95% CI, 0.5–1.1). In women, the reduction in CRC incidence was 50% for both distal CRC and proximal CRC (OR, 0.5; 95% CI, 0.3–0.9 for both) (Table 3.3.8).

In the population-based case–control study by Newcomb et al. (2003), screening with sigmoidoscopy was associated with a significant reduction in incidence (OR, 0.24; 95% CI, 0.17–0.33) for distal CRC, but not for proximal CRC (OR, 0.89; 95% CI, 0.68–1.16), up to 16 years of follow-up.

The study by Cotterchio et al. (2005) reported an overall incidence reduction with sigmoidoscopy of close to 50% (OR, 0.52; 95% CI, 0.34–0.80), with a strong reduction for distal CRC (OR, 0.41; 95% CI, 0.30–0.56) and a non-significant reduction for proximal CRC (OR, 0.72; 95% 0.51–1.01).

Doubeni et al. (2013) performed a case–control study of adults at average risk enrolled for at least 5 years in one of different health plans. CRC screening ascertainment was done by auditing electronic patient data files. In a population of just more than 1000 individuals, 92 case patients and 173 controls had undergone a screening sigmoidoscopy, resulting in an incidence reduction of 49% (OR, 0.51; 95% CI, 0.36–0.71) for overall CRC and of 74% (OR, 0.26; 95% CI, 0.14–0.49) for distal CRC, but no incidence reduction was found for proximal CRC (OR, 0.80; 95 CI, 0.52–1.25).

No protective effect was observed in the study by Kahi et al. (2014). The study of Kahi et al. (2014) primarily evaluated the protective effects of colonoscopy but reported non-significant associations between sigmoidoscopy and CRC incidence reduction after 5 years (OR, 0.75; 95% CI, 0.46–1.24) and 10 years (OR, 0.91; 95% CI, 0.68–1.23) of follow-up. [The figures were relatively small: only seven patients with distal CRC had undergone sigmoidoscopy in the 5-year window.]
With respect to the effect of sigmoidoscopy on CRC mortality, two relatively small, older case–control studies (with a total of 327 cases and 1064 controls) by Newcomb et al. (1992) and Selby et al. (1992) reported an association of having had a sigmoidoscopy screening examination with a decreased risk of CRC mortality, by approximately 80% (OR, 0.21; 95% CI, 0.08–0.52) for overall CRC (Newcomb et al., 1992) and by 59% (OR, 0.41; 95% CI, 0.25–0.69) for distal CRC (Selby et al., 1992). [The exposure was screening with rigid sigmoidoscopy in Selby et al. (1992).]

The association of a decreased risk of CRC mortality with sigmoidoscopy was not observed in the smaller study in the USA (Scheitel et al., 1999) (OR, 1.04; 95% CI, 0.21–5.13). Scheitel et al. (1999) found the same frequency of having had a sigmoidoscopy within 10 years of diagnosis in 218 cases (10.6%) and 435 controls (9.9%) and speculated that the low frequency could be the reason for a lack of a protective effect. In the study by Newcomb et al. (1992), the frequency of screening sigmoidoscopy was 10.6% in cases and 29.1% in controls, and in the study by Selby et al. (1992), the frequency was 8.8% in cases and 24.2% in controls.

A recently published case–control study of the effectiveness of endoscopy in a screening-eligible population in the USA (with 1747 cases and 3460 controls) (Doubeni et al., 2018) reported an overall CRC mortality reduction of 36% (OR, 0.64; 95% CI, 0.56–0.75) with sigmoidoscopy after extensive adjustment for potential confounders (e.g. matching and adjustments), with a strong preventive effect for CRC on both the distal and the proximal side of the colon (OR, 0.52; 95% CI, 0.41–0.66 for distal CRC and OR, 0.75; 95% CI, 0.62–0.92 for proximal CRC).

(b) Colonoscopy

There are few high-quality observational studies that have evaluated the preventive effects of colonoscopy screening in the population at average risk and even fewer that have evaluated incidence and mortality outcomes in current colonoscopy screening programmes. Most of the studies retrospectively evaluated colonoscopy by any indication or the quality indicators of the procedure (e.g. the ADR, which is a prerequisite for a screening programme to be effective but will not be highlighted in this section).

(i) Meta-analyses

The systematic review of observational studies of endoscopy (Brenner et al., 2014a) included three cohort studies and three case–control studies of colonoscopy (published in 2005–2014) in a meta-analysis of the effectiveness of colonoscopy screening. [All of the studies met the Working Group criteria except Nishihara et al. (2013) and Manser et al. (2012), both of which excluded prevalent cancers at baseline (included in Table 3.3.9). There was heterogeneity among the included studies, for example in the designs, in the study populations (four in the USA, one in Switzerland, and one in Germany), and in adjustment for confounders (from only 3 up to 14 variables) in the analyses, potentially biasing the effectiveness and maximum time frames of sigmoidoscopy before CRC diagnosis or mortality from 6–22 years.] The included studies are presented in Table 3.3.9 and Table 3.3.10.

The meta-estimates demonstrated a reduction of 69% (RR, 0.31; 95% CI, 0.12–0.77) in CRC incidence (five studies) and of 68% (RR, 0.32; 95% CI, 0.23–0.43) in CRC mortality (three studies) at any site. When stratified by anatomical location, the incidence reduction disappeared for either distal CRC or proximal CRC (RR, 0.21; 95% CI, 0.03–1.53 for distal CRC; RR, 0.44; 95% CI, 0.15–1.31 for proximal CRC). However, there was a mortality reduction of 82% (RR, 0.18; 95% CI, 0.10–0.31) for distal CRC and of 53% (RR, 0.47; 95% CI, 0.29–0.76) for proximal CRC.

<sup>b</sup> Of all screening modalities evaluated, not colonoscopy specifically.
In a population-based cohort study that estimated the preventive effects of colonoscopy in elderly people [study not included in the systematic review by Brenner et al. (2014a)], approximately 1,355,000 Medicare beneficiaries in the USA were prospectively followed up for 8 years (García-Albéniz et al., 2017). In the age group 70–74 years, the risk of CRC was 2.19% (95% CI, 2.00–2.37%) in those who had a screening colonoscopy, compared with 2.62% (CI, 2.56–2.67%) in the non-colonoscopy group, i.e. an absolute risk reduction of 0.42% (CI, 0.24–0.63%) for those who had a screening colonoscopy. In the age group 75–79 years, the risk of CRC was 2.84% in the colonoscopy group and 2.97% in the non-colonoscopy group (risk difference, −0.14%; CI, −0.41% to 0.16%). [The strength of the study is the large study population and the use of Medicare data to identify screening colonoscopies. Potential confounding factors are not adjusted for, but sensitivity analyses have been performed. Only one quarter of the individuals were followed up for longer than 5.5 years; this may be insufficient to adequately evaluate the protective effects of colonoscopy screening, but it could be valid for the older population studied.]

In another cohort study in the USA, the study population was generated from a diet and health study by the National Institutes of Health that sent questionnaires to people aged 50–71 years (Eldridge et al., 2013). The primary objective was to estimate the magnitude of uncontrolled confounding in observational studies by using medical records. Colonoscopy screening demonstrated a reduction in risk of CRC mortality of 60% (RR, 0.40; 95% CI, 0.30–0.55) after a mean follow-up of 11 years (Table 3.3.9). In a smaller follow-up study of a previous study that evaluated colonic neoplasia after a negative FOBT result (Rex et al., 1993), Kahi et al. (2009) followed up a population of approximately 700 individuals at average risk (mean age, 61 years); after a median follow-up of 8 years, 12 CRCs were diagnosed. Having had a screening colonoscopy decreased the risk of CRC incidence by 67% (SIR, 0.33; 95% CI, 0.10–0.62) and, statistically non-significantly, the risk of CRC mortality by 65% (SMR, 0.35; 95% CI, 0.00–1.06). [The study cohort did not have a concurrent control group, and observed rates of CRC incidence and mortality were compared with the expected rates from the Surveillance, Epidemiology, and End Results Program.]

(iii) Case–control studies

See Table 3.3.10.

In the study by Kahi et al. (2014) [study not included in the meta-analysis by Brenner et al. (2014a)], the protective effect of colonoscopy in reducing CRC incidence was observed for both the distal colon and the proximal colon. Kahi et al. (2014) demonstrated a 55% reduction in the incidence of distal CRC (OR, 0.45; 95% CI, 0.32–0.62) and a 35% reduction for proximal CRC (OR, 0.65; 95% CI, 0.46–0.92) in older United States veterans who had undergone a colonoscopy in the previous 10 years. The reduction in overall CRC incidence was 43% (OR, 0.57; 95% CI, 0.47–0.70). [The majority of colonoscopies were for diagnostic indications in a population of 99% men with an average age of > 80 years at diagnosis.] When estimated at 5 years, the point estimates were even lower (OR, 0.49; 95% CI, 0.39–0.61 for overall CRC; OR, 0.36; 95% CI, 0.25–0.53 for distal CRC; OR, 0.51; 95% CI, 0.35–0.76 for proximal CRC).

The study by Cotterchio et al. (2005), previously referred to among the case–control studies of sigmoidoscopy, also reported a reduction in CRC incidence in those who had undergone a screening colonoscopy. Cotterchio et al. (2005) did not observe any significant reduction in overall CRC incidence (OR, 0.69; 95% CI, 0.44–1.07) or proximal CRC incidence (OR, 1.02; 95% CI, 0.72–1.45), but observed a significant reduction (OR, 0.68; 95% CI, 0.49–0.94) in distal CRC incidence. [The study population was
relatively young (20–74 years), with few screening colonoscopies (4% in both groups).

In a case–control study by Brenner et al. (2014b), cases were recruited from 22 hospitals in the study region of Germany and matched with controls from population registries. Standardized personal interviews were used to retrieve information on previous colonoscopy and potential confounding factors. Having had a screening colonoscopy was associated with a reduction in CRC incidence by 91% (OR, 0.09; 95% CI, 0.07–0.13). Brenner et al. (2014b) stratified by sex and age and observed an association in both men (OR, 0.07; 95% CI, 0.05–0.12) and women (OR, 0.14; 95% CI, 0.08–0.23) and in both older individuals (≥ 70 years) (OR, 0.08; 95% CI, 0.05–0.13) and younger individuals (< 70 years) (OR, 0.11; 95% CI, 0.07–0.18). [The self-reported colonoscopies and their indications were validated by medical record audits, which varied in quality, and some misclassification of indication could be present.]

In the case–control study of screening-eligible members of the Kaiser Permanente Medical Care Program in the USA, a preventive effect of colonoscopy on CRC mortality was observed for both distal CRC and proximal CRC (Doubeni et al., 2018). For the association of having had a colonoscopy within 10 years and reduced CRC mortality, the odds ratio was 0.25 (95% CI, 0.12–0.53) for distal CRC and 0.35 (95% CI, 0.18–0.65) for proximal CRC. For the association of having had a colonoscopy within 10 years and reduced overall CRC mortality, the odds ratio was 0.33 (95% CI, 0.21–0.52) (Table 3.3.10).

(c) Other measures of performance

A decreased incidence of late-stage CRC is an intermediate measure of screening effectiveness. One case–control study of the population at average risk (471 cases, 509 controls) by Doubeni et al. (2013), previously referred to, evaluated the association between colonoscopy screening and the risk of late-stage CRC. For having undergone a screening colonoscopy up to 10 years before the reference date, the odds ratio was 0.30 (95% CI, 0.15–0.59) for late-stage CRC (stage IIB–IV). Sigmoidoscopy screening was performed in 19.5% of the cases and in 34.0% of the controls, with an associated reduction in the risk of late-stage distal CRC (OR, 0.26; 95% CI, 0.14–0.49) but not of late-stage proximal CRC (OR, 0.80; 95% CI, 0.52–1.25). [The generalizability of the result of the study is limited because of its case–control design. Screening colonoscopies were relatively uncommon at the beginning of the study, and there is potential for unmeasured and unadjusted residual confounders.]

3.3.4 Adverse effects

(a) False-positive results

Screening techniques are intended for the screening of large numbers of asymptomatic individuals at average risk, and the ultimate goal is further stratification, not final diagnosis. As a result, identifying a small number of cases of cancers and/or precancerous lesions in a large population may, by necessity, result in large numbers of false-positive results.

(i) Sigmoidoscopy

The criteria for referral to colonoscopy vary widely among sigmoidoscopy-based screening strategies, because of a lack of consensus about which features of distal lesions predict the risk of advanced proximal neoplasms (Castells et al., 2013). A proportion of individuals who undergo a screening sigmoidoscopy that results in a follow-up colonoscopy will ultimately not be diagnosed with any cancerous or precancerous lesions. [Such false-positive results are not well reported in studies. Therefore, the total number and/or percentage of referrals in these studies are reported here.] The proportion of patients referred for colonoscopy ranged from 5.2% to 23.4% in the RCTs of sigmoidoscopy (Table 3.3.11).

NORCCAP, Norwegian Colorectal Cancer Prevention trial; PLCO, Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial; PPV, positive predictive value; SCORE, Screening for Colon and Rectum trial; UKFSST, United Kingdom Flexible Sigmoidoscopy Screening Trial.

\(^a\) False-positive rate can be calculated as (1 – PPV)\(^b\)100.

\(^b\) For PLCO in subjects without distal cancer.

\(^c\) For UKFSST, advanced distal lesions defined as a ≥ 10 mm polyp, ≥ 3 adenomas, tubulovillous or villous adenoma, severe dysplasia malignancy, or ≥ 20 hyperplastic polyps above the distal rectum, as determined by screening sigmoidoscopy and associated biopsies; for SCORE, advanced distal lesions defined as a ≥ 10 mm adenoma, tubulovillous or villous adenoma, or severe dysplasia, as determined by screening sigmoidoscopy and associated biopsies; for PLCO, advanced distal lesions defined as a ≥ 10 mm adenoma, tubulovillous or villous adenoma, or severe dysplasia in rectum, sigmoid colon, or descending colon or within 50 cm from anal verge (if segment not specified), as determined by diagnostic follow-up procedures completed within 1 year of screening.

\(^d\) For UKFSST, proximal to sigmoid colon; for SCORE, proximal to the descending colon or in the descending colon, if not detected at screening sigmoidoscopy; for PLCO, segment proximal to descending colon or more than 50 cm from anal verge (if segment not specified).

\(^e\) For NORCCAP, proximal lesions were included.

\(^f\) The denominator to calculate the percentage of true-positives were individuals with a positive screen regardless of whether they underwent a colonoscopy.

Adapted from Weissfeld et al., Flexible sigmoidoscopy in the PLCO cancer screening trial: results from the baseline screening examination of a randomized trial, *JNCI: Journal of the National Cancer Institute*, 2005, volume 97, issue 13, pages 989–997, adapted by permission of Oxford University Press (Weissfeld et al., 2005).
Results are available online from population-based programmes in Italy (Osservatorio Nazionale Screening, 2017) and the United Kingdom (Bowel Cancer Screening Southern Programme Hub; National Health Service, 2015). In Italy, approximately 50,000 individuals aged 55 years were offered sigmoidoscopy for CRC screening for 2014, and the percentage of patients who met the criteria for referral for colonoscopy was 10.9%. The roll-out of the sigmoidoscopy programme in the United Kingdom started in 2013. In 2014, 12 of 18 screening centres of the Bowel Cancer Screening Southern Programme Hub invited individuals older than 55 years for a single sigmoidoscopy ($n = 8433$). On average, 5.2% of those screened were referred for colonoscopy, although some variability was observed between centres, with referral rates ranging from 2.8% to 11.5%.

(ii) Colonoscopy

False-positive results are not an issue for primary colonoscopy screening, in which, if it is appropriate, polyps can be removed during the screening procedure and no further assessment is required.

(b) Overdiagnosis

Overdiagnosis refers to the detection of cancerous or precancerous lesions that would not, in the absence of screening, have caused symptoms or death in the individual’s lifetime (Esserman et al., 2014).

(i) Sigmoidoscopy

There are no publications that address overdiagnosis of CRC via sigmoidoscopy screening.

(ii) Colonoscopy

Brenner et al. (2015) estimated the probabilities of prevention of CRC, early detection of CRC, or overdiagnosis of CRC according to sex and age at screening colonoscopy. This was the first and only attempt to date to estimate overdiagnosis from a national CRC screening programme. In the analysis of Brenner et al. (2015), the proportion of overdiagnosis among CRCs detected with screening colonoscopy was 11% in men and 8% in women overall, and 7% in men and 4% in women for screening colonoscopies in individuals younger than 70 years. [The Working Group noted that the validity of their calculations depends on the validity of the assumed transition rates from adenomas to CRCs. Even a small change in these rates would result in a large change in the estimated proportion of overdiagnosis. Therefore, the Working Group considered that the level of overdiagnosis is uncertain.]

Yang et al. (2014) calculated the difference between the observed CRC incidence and an expected baseline incidence for each year from 1979 to 2009. Then, for each year, they multiplied the difference in incidence by the number of individuals aged 50 years and older in the same year. Finally, they summed the results for each year from 1979 to 2009. This was similar to the approach used by Bleyer & Welch (2012) to estimate the number of breast cancers overdiagnosed because of mammography screening. Yang et al. (2014) concluded that there is probably little overdiagnosis of CRC. [The Working Group noted that this study has little validity, because (i) it only demonstrates that the preventive effect of CRC screening is higher than the rate of overdiagnosis and (ii) it is of ecological design.]

(c) Endoscopy-related complications

Endoscopy-related complications can occur immediately or several days after the procedure. Although endoscopy services must have processes in place to identify and record adverse outcomes that occur after the patient leaves the endoscopy unit, the accurate identification of those events that occur after the patient is dismissed from the endoscopy unit is still a challenge. Late complications may still be underestimated because of underreporting.

The following complications in CRC screening with sigmoidoscopy or colonoscopy are...
defined as serious: death within 30 days or hospitalization within 30 days (because of serious haemorrhage involving transfusion, or because of perforation, vagal syndrome, or peritonitis-like syndrome as a consequence of primary screening with endoscopic techniques) (Segnan et al., 2010). [Because serious harms from endoscopy other than perforation and bleeding are not routinely reported or defined, the reported rates of serious harms are of limited value.] On the basis of a few large-scale studies, the mortality rate within 30 days associated with endoscopic procedures was estimated to be 1 in 15 000 (Bacchus et al., 2016).

(i) Sigmoidoscopy

Compared with colonoscopy, sigmoidoscopy has fewer adverse effects, requires less bowel preparation, and poses a lower risk of bowel perforation (Lin et al., 2016a). Physical adverse effects of the screening procedure and of colonoscopy follow-up were reported in all the RCTs of CRC screening with sigmoidoscopy (Table 3.3.12 and Table 3.3.13, respectively) but only partly in the PLCO trial in the USA (Schoen et al., 2012). There was incomplete reporting of deaths related to the follow-up colonoscopy and surgery (Holme et al., 2013).

Lin et al. (2016a) reported harms from different CRC screening methods in pooled analysis using observational studies and RCTs. In a population at average risk, perforations from sigmoidoscopy were relatively uncommon (0.1 per 1000 procedures; I² = 18.4%), as were episodes of major bleeding (0.2 per 1000 procedures; I² = 52.2%). The risk of complications increased markedly in examinations where a polypectomy was performed. In a large prospective, multicentre study that focused on colonoscopy polypectomy, major bleeding complications occurred in 1.6% of the examinations, and the perforation rate was 1.1%. Large polyp size and distal polyp location were found to be significant risk factors for major complications (OR, 2.40; 95% CI, 1.34–4.28 for distal polyp location) (Heldwein et al., 2005).

Recent studies in sigmoidoscopy screening settings showed that the procedure was well tolerated by most participants (Blom et al., 2004; Viiala & Olynyk, 2007; Robb et al., 2012; Bevan et al., 2015). Robb et al. (2012) reported that the most common side-effect that reached moderate or severe levels was wind (16%); abdominal pains and cramps were the next most commonly reported side-effect (7%). Compared with men, women found the procedure more uncomfortable and had a smaller average depth of insertion, which is determined mainly by patient tolerance (Eloubeidi et al., 2003; Viiala & Olynyk, 2008).

(ii) Colonoscopy

Major complications were reported in two of the four trials of colonoscopy screening currently under way. In the Nordic-European Initiative on Colorectal Cancer (NordICC) trial (Bretthauer et al., 2016), 1 screened individual had a colonoscopy perforation at the baseline screen (0.08 per 1000 procedures), and 18 individuals developed bleeding due to polypectomy (1.5 per 1000 procedures). No deaths or other major complications related to the screening intervention occurred within 30 days after screening. A total of 51 screened individuals experienced minor vasovagal reactions during colonoscopy (4.1 per 1000 procedures). However, all complications were short-term, and none required extra measures for the patient after the procedure.

Of the major complications reported at baseline in the COLONPREV trial (Quintero et al., 2012), 12 individuals developed bleeding (2.4 per 1000 procedures) and 1 individual had a colonoscopy perforation (0.2 per 1000 procedures). Other serious adverse events were reported: 10 individuals experienced hypotension or bradycardia (2.0 per 1000 procedures), and 1 individual had desaturation (0.2 per 1000 procedures).

Three meta-analyses of population-based studies aimed at estimating complications and
risk factors for colonoscopy have been published recently (Lin et al., 2016a; Reumkens et al., 2016; Vermeer et al., 2017). In two of them, major bleeding occurred in 0.8 per 1000 procedures (Lin et al., 2016a; Vermeer et al., 2017). In contrast, Reumkens et al. (2016) reported overall post-colonoscopy bleeding in 2.4 per 1000 procedures. The perforation rate for screening or surveillance colonoscopies ranged from 0.07 per 1000 procedures to 0.4 per 1000 procedures (Lin et al., 2016a; Reumkens et al., 2016; Vermeer et al., 2017). Reumkens et al. (2016) found that perforation rates for screening or surveillance colonoscopies were about one quarter those for diagnostic examinations in symptomatic patients (0.3 per 1000 procedures vs 1.3 per 1000 procedures; \( P < 0.001 \)), because of a population at average risk with fewer findings that required diagnostic or therapeutic interventions.

Other severe complications that require hospitalization are not consistently reported. Two studies that evaluated harms in people who received colonoscopy versus those who did not found no increased risk of myocardial infarction, cerebrovascular accident, or other cardiovascular events as a result of colonoscopy (Warren et al., 2009; Stock et al., 2013).

The risks of less serious complications, such as self-limited bleeding or abdominal pain, are less well documented than major complications after colonoscopy. One third of individuals who undergo a colonoscopy may report some gastrointestinal symptoms after the procedure (Zubarik et al., 1999; Bini et al., 2003; Ko et al., 2007). Reported symptoms include abdominal pain (10.5%), bloating (25%), self-limited gastrointestinal bleeding (3.8%), diarrhoea (6.3%), and nausea (4.0%). These symptoms generally are mild and resolve within 2 days after colonoscopy (Ko & Dominitz, 2010). Screening colonoscopy performed with conscious sedation is associated with less patient-reported abdominal discomfort compared with screening sigmoidoscopy without conscious sedation (Zubarik et al., 2002).

Findings from systematic reviews suggested similar tolerability, based on the number of minor adverse events, no difference in efficacy of bowel preparation, and no differences in the number and type of clinically significant adverse events between colon cleansing regimens (such as polyethylene glycol solution, oral sodium phosphate solution, sodium picosulfate or magnesium citrate, and enemas) (Tan & Tjandra, 2006; Belsey et al., 2007).

Complications from conscious sedation for colonoscopy are also uncommon but include respiratory depression, hypoxia, chest pain, cardiac arrhythmias, hypotension or hypertension, and vasovagal reactions (Ko & Dominitz, 2010). Sharma et al. (2007) found an overall risk of cardiopulmonary complications after colonoscopy of 1.1%.

(d) Psychosocial harms

Short-term or long-term adverse psychosocial consequences of factors related to cancer screening can occur in any phase of the screening programme. Most of the evidence about the psychological effects of being screened was derived from RCTs and was reported according to the individuals’ screening results.

(i) Sigmoidoscopy

False-positive results have the potential to cause symptoms of anxiety, distress, and depression as well as changes in the overall perception of one’s health status (Kirkøen et al., 2016), and therefore individuals who have had a false-positive result may be more reluctant to undergo successive screening. In results from RCTs, the psychological consequences in individuals who were found not to have advanced neoplasia have been reported to be transient (Wardle et al., 2003; Taylor et al., 2004; Miles et al., 2009; Kapidzic et al., 2012). Furthermore, the pilot study of a national screening programme for CRC in Norway showed that a positive screening result did not increase participants’ levels of anxiety.

or depression, or decrease participants’ levels of health-related quality of life (Kirkøen et al., 2016).

Psychological distress derived from a true-positive screening result (i.e. being labelled as sick or at risk) should not be dismissed. Nevertheless, among participants with a positive sigmoidoscopy result, Kapidzic et al. (2012) found similar quality of life scores in those with negative or positive colonoscopy results. Possible explanations for these mainly positive effects of CRC screening in participants with a true-positive result could be that although the participants were worried about the possibility of having CRC, when polyps were detected they were also relieved that the polyps were detected early and that they would be screened regularly to prevent CRC, or when CRC was detected they were reassured because they soon underwent treatment. In the case of a false-positive screening result, the authors hypothesized that the participants were relieved because no abnormalities were found during further investigations.

Robb et al. (2012) examined changes in anxiety levels and self-rated health from before screening to follow-up among participants in a population-based sigmoidoscopy screening programme. No significant changes were found for either anxiety levels or self-reported health. Results did not differ by sex, deprivation index, ethnicity, or screening outcome, and satisfaction with the screening process was high.

In contrast, another study reported that the level of anxiety was directly correlated with levels of pain and discomfort after the procedure and was inversely related to the level of satisfaction. Better management of anxiety may lead to higher procedural comfort in procedures performed without sedation (Carter et al., 2013).

(ii) Colonoscopy

There is little evidence about adverse psychological effects of colonoscopy among the screened population as a whole (Thiis-Evensen et al., 1999b; Taupin et al., 2006).

(e) False reassurance

It has been suggested that receiving a negative screening result may cause false reassurance or have a “certificate of health” effect. False reassurance in participants who receive a negative screening result may cause them to wrongly believe that they are at lower risk of the disease, and they may therefore be less likely to engage in health-related behaviours that would lower their risk and/or be less alert to symptoms that may appear or to the need for further evaluation.

(i) Sigmoidoscopy

Short-term effects on lifestyle and health attitudes were addressed in two reports from the trial in the United Kingdom (Miles et al., 2003; Wardle et al., 2003), and no negative effects were detected. Adverse effects on lifestyle were evaluated prospectively in a randomized controlled study within the NORCCAP trial (Larsen et al., 2007). After 3 years, those who had been screened reduced their intake of fruit, berries, and vegetables, did not follow the trend of increased frequency of physical exercise seen for controls, gained more weight than controls, and did not improve their smoking habits as successfully as did the controls not invited for screening. Also, normal findings at screening (i.e. no neoplasia) were associated with a subsequent statistically significant gain in body weight compared with subjects with positive screening results. These findings persisted after adjustment for confounding factors.

(ii) Colonoscopy

No studies are available on false reassurance in colonoscopy screening.
The extent to which false reassurance plays a role in CRC screening with endoscopy remains unclear. There are no known studies that have examined the phenomenon of delayed presentation of symptoms after endoscopy screening for CRC.

\[(f)\] **Time/effort and opportunity costs**

For all aspects of participation in the screening process, depending on the health-care system, there are time/effort and opportunity costs (non-financial harms) for the participant, as well as potential financial harms to the participant or family or psychological harm from anticipation of future financial costs related to screening (PDQ Screening and Prevention Editorial Board, 2017).

\[(i)\] **Sigmoidoscopy**

There are no studies available that have aimed to address time/effort and opportunity costs derived from participating in a sigmoidoscopy screening programme.

\[(ii)\] **Colonoscopy**

Two small studies have examined time off from work among asymptomatic individuals undergoing colonoscopy. Ko *et al.* (2007) reported that 69.3% of individuals who underwent colonoscopy for CRC screening, surveillance, or follow-up of another abnormal screening result lost at least 1 day from their normal activities for the colonoscopy preparation, procedure, or recovery. About 25% of individuals reported that their family or friends lost at least 1 day from their normal activities because of the procedure. Dong *et al.* (2011) observed that one third of the participants who worked and who underwent midweek screening colonoscopy missed work on days in addition to the day of the procedure. Unanticipated time missed from work could increase the indirect costs of screening colonoscopy.

### 3.3.5 Benefit–harm ratio

In this section, the benefit–harm ratio of endoscopy screening is described. Endoscopy screening, like all other forms of screening, is associated with both benefits and harms (see Section 3.3.2, Section 3.3.3, and Section 3.3.4). It is the balance between these benefits and harms that determines whether a particular form of screening is worthwhile (see Section 3.1).

\[(a)\] **Systematic review and decision modelling for USPSTF**

In 2016, a systematic review (Lin *et al.*, 2016a, b) and decision analysis (Knudsen *et al.*, 2016) of benefits and harms of screening were published alongside the USPSTF recommendations for CRC screening. These studies provide a way to initially assess the benefit–harm ratio of endoscopy screening. The systematic review demonstrated that harms of colonoscopy were greater than those of sigmoidoscopy and may also include harms from bowel preparation and sedation (Lin *et al.*, 2016a, b). Reported harms were mostly proportional to the number of colonoscopies performed with screening. Therefore, in the USPSTF decision analysis, the benefit–harm ratio of screening was expressed as the number of colonoscopies that needed to be performed for every life year gained. This decision analysis showed that repeated colonoscopy at ages 50 years, 60 years, and 70 years could result in 250–275 life years gained per 1000 individuals aged 40 years requiring an average of just more than four colonoscopies in a lifetime (including surveillance colonoscopies). These numbers correspond to 14.5–16.5 colonoscopies per life year gained. The efficiency ratio (i.e. the ratio of incremental colonoscopies per additional life year gained compared with a less intensive colonoscopy strategy) varied between 39 and 65 colonoscopies per life year gained.
(b) QALYs and DALYs from modelling studies

[The Working Group noted that the estimates described in this section are based on Markov models, which mostly assume that the additional adenomas detected by colonoscopy have similar progressive potential to those detected by sigmoidoscopy, and that colonoscopy screening will therefore be more effective than sigmoidoscopy screening. Therefore, all results in the following section should be interpreted with caution.]

Seventeen studies evaluated the impact of endoscopy screening on QALYs or life expectancy (Table 3.3.14). [Most of these studies were conducted in settings characterized by high background cancer incidence rate. As described in Section 3.1.5, benefit–harm ratios depend heavily on this background cancer incidence rate. Therefore, the results of these studies may not easily be transferable to settings characterized by low cancer incidence rate.] All of the studies concluded that screening influenced QALYs positively and resulted in a net gain in QALYs (Table 3.3.14). The QALYs gained for colonoscopy varied substantially, from 17 QALYs per 1000 individuals in a study in Singapore (Dan et al., 2012) to 611 QALYs per 1000 individuals in a study in Hong Kong Special Administrative Region, China (Wong et al., 2015). [The Working Group raised some doubts about the validity of this value.] For sigmoidoscopy, the net benefit of screening was slightly lower than that for colonoscopy, varying from 5 QALYs gained per 1000 individuals (Dan et al., 2012) to 124 QALYs gained per 1000 individuals (Lam et al., 2015). The wide variability in estimates can be explained partly by the age of the population to which the estimates were standardized and partly by variation in disease risk. When studies with questionable validity or young and mixed-age populations were excluded, the reported range in QALYs gained narrowed considerably, to 50–125 QALYs per 1000 individuals for colonoscopy and 65–125 QALYs per 1000 individuals for sigmoidoscopy. All of the studies consistently showed a net gain in QALYs, indicating a favourable balance between benefits and harms of CRC screening. [The Working Group placed an important caveat on these estimates: 11 studies only took the impact of CRC diagnosis on quality of life into account. The impacts of other harms of screening, such as adverse events, false-positive results, and anxiety, were not considered. Three studies did consider some other harms of screening, such as the disutility of knowledge of being an adenoma patient (Lam et al., 2015; Wong et al., 2015) or the disutility of undergoing colonoscopy and experiencing adverse effects (van Hees et al., 2014b). None of the studies considered in their estimates of QALYs the anxiety associated with screening and diagnostic follow-up or the potential negative impact of a negative screening result on an increased risk of adopting an unhealthy lifestyle.] Of the studies that evaluated 10-yearly colonoscopy and 5-yearly sigmoidoscopy, four found higher QALYs with colonoscopy than with sigmoidoscopy (Heitman et al., 2010; Dan et al., 2012; Sharaf & Ladabaum, 2013; Kingsley et al., 2016). [As noted before, these results should be interpreted with caution because all of these models would have assumed a higher effectiveness of colonoscopy screening compared with sigmoidoscopy screening.]

Only two studies evaluated the impact of endoscopy screening on DALYs (Woo et al., 2007; Ginsberg et al., 2012) (Table 3.3.15). Both studies found endoscopy screening to result in a net decrease in DALYs, ranging from 0.3 to 10 DALYs averted for sigmoidoscopy and from 0.6 to 9 DALYs averted for colonoscopy. [However, again, only one study considered the negative impact of screening on DALYs, taking into account years of life lost because of complications of screening. Disability from adverse effects, anxiety, false-positive results, and adenoma diagnosis could not be taken into account, because disability coefficients for such events have not been established.]

DALYs, disability-adjusted life years; FOBT, faecal occult blood test; NR, not reported.

a In the WHO classification, sub-Saharan Africa and South-East Asia, including those countries with very high adult mortality and high child mortality, are referred to as AfrE and SearD, respectively.

b Signifies the population at the start of the simulation, i.e. cohort age 50 years signifies a population of people aged 50 years that are followed up until death or a certain age, and cohort age 50–75 years signifies a population of people aged 50–75 years that are followed up until death or for a certain period.
[The lack of consideration of disability and disutility of the harms of screening itself in the above-mentioned studies probably reflects the lack of studies assessing the impact of the screening process on quality of life. The one study that included burden of screening and diagnostic follow-up in QALYs estimates used disutility values obtained by making assumptions because estimated values are lacking.] Only one study has directly assessed the burden of colonoscopy in a time-trade-off analysis. That study suggested that the number of days of life that individuals are willing to give up to avoid having to undergo screening depends on screening status (Dominitz & Provenzale, 1997). Those who had not been screened were willing to give up a median of 91 days to avoid screening sigmoidoscopy and 183 days to avoid screening colonoscopy. However, those who had already been screened were not willing to give up any time to avoid screening, indicating that the impact of the screening examination on quality of life was negligible for those individuals. A study in Hong Kong Special Administrative Region, China, evaluated health-related quality of life after diagnosis with colorectal neoplasia (Lam et al., 2015). Interestingly, quality of life was higher in patients with adenomas than in the Hong Kong reference population. [The better quality of life in this patient group probably reflects a “healthy screenee effect”: those who participate in screening are on average healthier than the average population and therefore experience better health-related quality of life.] The outcomes of these studies indicate the difficulty of obtaining reliable estimates of the impact of screening on quality of life, and therefore of weighing the benefits of screening against its harms.]

### 3.3.6 Cost–effectiveness studies

#### (a) Background

[Like estimates of QALYs and DALYs, cost–effectiveness estimates are based mostly on Markov models, assuming that the benefits of colonoscopy screening are larger than those of sigmoidoscopy screening. Therefore, comparative results should be interpreted with caution. Several studies have been published that assessed the cost–effectiveness of CRC screening. The majority of these studies have been conducted in high-income countries, which are often characterized by high background cancer incidence rate. As described in Section 3.1.5, cost–effectiveness estimates depend heavily on this background cancer incidence rate and local costs. Therefore, the results of these studies may not easily be transferable to other settings, such as low- and middle-income countries.]

#### (b) Cost–effectiveness studies and systematic reviews

The literature on this topic has been summarized in three systematic reviews that used similar methodology, in 2002, 2011, and 2015 (Table 3.3.16) (Pignone et al., 2002; Lansdorp-Vogelaar et al., 2011; Patel & Kilgore, 2015). The reviews followed a similar methodology except that the review by Lansdorp-Vogelaar et al. (2011) also included studies outside the USA. This description of the cost–effectiveness of CRC screening is based on these reviews and supplemented with individual studies published since then.

Pignone et al. (2002) included seven studies in the USA that evaluated cost–effectiveness of CRC screening with endoscopy. Six studies considered life years gained as the outcome without adjustment for quality of life. Only the study by Ness et al. (2000) considered quality of life, but it did not include disutility for the burden of screening, adverse events, and false-positive results. All of the studies found endoscopy screening to cost

* Estimates for cost–effectiveness depend on background cancer incidence. Therefore, estimates may not easily be transferable to low-incidence settings.
less than US$ 50 000 per life year gained. One study showed that sigmoidoscopy screening could potentially even be cost saving in a dedicated screening setting (Loeve et al., 2000). For the remainder of studies, costs per life year gained varied between less than US$ 5000 and US$ 40 000 per life year gained. Three of five studies that evaluated both strategies found that colonoscopy dominated sigmoidoscopy (i.e. it was both more effective and had lower costs per life year gained). One study found both strategies to be cost-effective, and one study found that colonoscopy was dominated by the combination of sigmoidoscopy plus FOBT.

The systematic review by Lansdorf-Vogelaar et al. (2011) included 16 studies that evaluated the cost–effectiveness of sigmoidoscopy and/or colonoscopy screening. The review found wide variability in the estimated cost–effectiveness of endoscopy screening across studies. Twelve studies estimated cost–effectiveness of sigmoidoscopy compared with no screening. In two studies, sigmoidoscopy screening was found to be cost saving, whereas in one study, costs per QALY gained were as high as US$ 56 600. Sixteen studies assessed the cost–effectiveness of colonoscopy screening compared with no screening. In two studies, sigmoidoscopy screening was found to be cost saving, whereas in one study, costs per QALY gained were as high as US$ 56 600. Sixteen studies assessed the cost–effectiveness of colonoscopy screening compared with no screening; five of the studies found colonoscopy screening to be cost saving. At a willingness-to-pay threshold of US$ 100 000 per QALY gained, all of the studies found sigmoidoscopy screening and/or colonoscopy screening to be cost-effective compared with no screening. At a threshold of US$ 50 000 per QALY gained, only one study found sigmoidoscopy screening not to be cost-effective. As expected, all of the studies that evaluated both strategies found that colonoscopy screening was more effective than sigmoidoscopy screening. Approximately half of the studies also found that colonoscopy screening cost less per QALY gained and therefore dominated sigmoidoscopy screening. For the other half of the studies, the incremental costs per life year gained for colonoscopy screening compared with sigmoidoscopy screening varied between US$ 1000 and US$ 85 000, and at a willingness-to-pay threshold of US$ 100 000 per life year gained, colonoscopy screening would be considered cost-effective.

The review by Patel & Kilgore (2015) identified 13 studies in the USA in addition to the studies included in the review of Lansdorp-Vogelaar et al. (2011). [It must be noted that there was overlap in the models used between different studies.] Six independent models evaluated 5-yearly sigmoidoscopy screening. Four concluded that this strategy was less costly and more effective than no screening. In the other two models, costs were less than US$ 31 000 per life year gained. Eleven independent models evaluated 10-yearly colonoscopy screening. Three models found this strategy to be cost saving, whereas the cost–effectiveness ratio was less than US$ 30 000 per life year gained for the remainder of the strategies. In the comparison across these sigmoidoscopy and colonoscopy strategies, only two of seven models concluded that the incremental costs per life year gained for colonoscopy screening compared with sigmoidoscopy screening exceeded US$ 50 000.

Since the review by Patel & Kilgore (2015), two new models have been published on the cost–effectiveness of CRC screening in the USA (Kingsley et al., 2016; Barzi et al., 2017), and two models have published updated results (Hassan & Gralnek, 2015; Ladabaum & Mannalithara, 2016) (Table 3.3.17). The findings of these studies were consistent with those of Patel & Kilgore (2015) and demonstrated cost–effectiveness ratios of both sigmoidoscopy screening and colonoscopy screening not exceeding US$ 15 000 per QALY gained. Kingsley et al. (2016) and Barzi et al. (2017) provided estimates for both sigmoidoscopy screening and colonoscopy screening and showed that colonoscopy screening was more effective than sigmoidoscopy screening. Kingsley et al. (2016) found colonoscopy also to be more costly, with an incremental cost–effectiveness ratio of less than US$ 50 000 per QALY gained,

LYG, life year gained; LYs, life years; NR, not reported; QALYs, quality-adjusted life years; SAR, Special Administrative Region; yr, year or years.

<sup>a</sup> Includes studies published after Patel & Kilgore (2015) (for studies in the USA) or published after Lansdorp-Vogelaar et al. (2011) (for studies outside the USA).

<sup>b</sup> Signifies the population at the start of the simulation, i.e. cohort age 50 years signifies a population of people aged 50 years that are followed up until death or a certain age, and cohort age 50–75 years signifies a population of people aged 50–75 years that are followed up until death or for a certain period.

<sup>c</sup> Estimates for QALYs gained and cost–effectiveness depend on background cancer incidence. Therefore, estimates may not easily be transferable to low-incidence settings.

<sup>d</sup> Reported mortality reduction for 100% participation.
whereas Barzi et al. (2017) found colonoscopy to be more cost saving than sigmoidoscopy.

Since the review by Lansdorp-Vogelaar et al. (2011), 12 new studies have been published that evaluated the cost–effectiveness of endoscopy screening outside the USA: two in Canada (Heitman et al., 2010; Telford et al., 2010), four in Europe (Sharp et al., 2012; Whyte et al., 2012; Ladabaum et al., 2014; Aronsson et al., 2017), and six in Asia (including the Middle East) (Barouni et al., 2012; Dan et al., 2012; Wang et al., 2012; Lam et al., 2015; Wong et al., 2015; Sekiguchi et al., 2016). Sigmoidoscopy screening was evaluated in seven studies, and colonoscopy screening was evaluated in 10 studies. All of the studies found cost–effectiveness ratios of less than US$ 35 000 per QALY gained. Five studies evaluated both sigmoidoscopy screening and colonoscopy screening, and all of them found that 10-yearly colonoscopy was more effective than 5-yearly sigmoidoscopy (Heitman et al., 2010; Dan et al., 2012; Lam et al., 2015; Kingsley et al., 2016; Barzi et al., 2017). In the other studies, the incremental costs per life year gained moving from sigmoidoscopy screening to colonoscopy screening were less than US$ 35 000.

[Overall, there is high variability in the estimates for cost–effectiveness across these studies. The reviews tried to standardize as much as they could across the studies, either by including only studies in the USA (Pignone et al., 2002; Patel & Kilgore, 2015) or by converting all currencies into United States dollars (Lansdorp-Vogelaar et al., 2011). However, the variability is high even between studies in the USA. All of the authors of the cost–effectiveness reviews mentioned differences in assumptions about natural history, screening characteristics, and screening participation as potential reasons for differences in model outcomes (Pignone et al., 2002; Lansdorp-Vogelaar et al., 2011; Patel & Kilgore, 2015). Limited empirical evidence hinders the assessment of which set of assumptions is the most plausible. In addition, despite recommendations from the Panel on Cost-Effectiveness in Health and Medicine (Weinstein et al. 1996), the studies still differ widely with respect to perspective, population, time horizon, and discount rate, introducing another reason for differences between the studies (Lansdorp-Vogelaar et al., 2011).]

[Although the majority of the studies indicate that colonoscopy screening is more effective and less costly than sigmoidoscopy screening, these results may be biased in favour of colonoscopy. As explained previously, the models estimated a higher effectiveness of colonoscopy by assumptions, and the lower costs may result from higher savings due to treatment avoided because of higher effectiveness as well as from the shorter interval for screening sigmoidoscopy than for screening colonoscopy in the modelling studies. As shown in RCTs, the interval for sigmoidoscopy can be safely extended to at least 10 years without attenuation of its protective effect (Atkin et al., 2010; Segnan et al., 2011; Schoen et al., 2012; Holme et al., 2014).]

(c) Additional cost–effectiveness considerations

(i) Lower age limit of screening

Very few studies have assessed the optimal age at which to start CRC screening. Two studies have assessed the optimal timing for a single endoscopy to gain the most QALYs. The first study (Ness et al., 2000) found that a single colonoscopy between age 50 years and age 54 years was cost-effective both compared with no screening and compared with colonoscopy at older ages. For men, colonoscopy between age 45 years and age 49 years may also be cost-effective for a willingness-to-pay threshold exceeding US$ 69 000 per QALY gained. The second study (Whyte et al., 2012) assessed the optimal age for a single sigmoidoscopy and found that sigmoidoscopy at age 55 years was associated with the greatest gain in QALYs compared with sigmoidoscopy at older
ages. However, results for a single sigmoidoscopy at any age between 52 years and 58 years resulted in very similar QALYs gained. The results for a single sigmoidoscopy at ages younger than 52 years and older than 58 years showed that the QALYs gained decreased, and these alternatives were not found to be cost-effective.

The Cancer Intervention and Surveillance Modeling Network (CISNET) performed a decision analysis for the USPSTF to determine the optimal age at which to start, the optimal age at which to stop, and the optimal interval for CRC screening (Knudsen et al., 2016). The models suggested that starting CRC screening at age 45 years, rather than at age 50 years, yielded a modest increase in life years gained and had a more favourable balance between life years gained and the clinical burden of colonoscopies. For colonoscopy screening, two of the three models found that performing colonoscopy every 15 years from age 45 years resulted in slightly more life years gained compared with colonoscopy every 10 years from age 50 years without increasing the lifetime number of colonoscopies. However, one model estimated a slight loss in life years gained with a longer screening interval and an earlier age to start screening. On the basis of these discordant findings, the USPSTF concluded that there was insufficient evidence to support a starting age of 45 years for the general population, especially given the lack of empirical evidence of screening in the younger population.

Finally, one study assessed whether the optimal age at which to start colonoscopy screening varied by race and sex (Lansdorp-Vogelaar et al., 2009). This study showed that although the risks of CRC incidence and mortality in women reach levels comparable to those in men 4–8 years later in life, the optimal age at which to start screening does not differ by sex. This finding can be explained by the longer life expectancy in women: the number needed to screen to detect one advanced adenoma may be higher in women than in men, but the number of detected advanced adenomas needed to prevent one case of CRC is lower in women than in men. This makes the number needed to screen to prevent one CRC case similar for men and women. However, the study did show that the optimal age at which to start screening was approximately 5 years earlier for African Americans (age 47 years) than for Whites (age 53 years) for both men and women.

(ii) Upper age limit of screening

Few studies have assessed the optimal age at which to stop screening. Maheshwari et al. (2008) performed a life-table analysis to estimate the impact of prematurely stopping screening compared with the maximal potential benefit from lifelong screening. They concluded that stopping screening at approximately age 82 years would retain 80% of the maximal clinical benefit of screening. However, this analysis was based on the risk of dying from CRC among older people and did not take into account the impact of previous screening on this risk.

In the decision analysis for the USPSTF, the CISNET models also evaluated the optimal age at which to stop screening. Screening strategies were compared, with stopping ages varying between 75 years, 80 years, and 85 years (Knudsen et al., 2016). The models showed that in individuals who were consistently screened from age 50 years onwards, the life years gained associated with extending the age at which to stop screening beyond age 75 years were generally small relative to the number of additional colonoscopies required. Therefore, it was concluded that age 75 years would be a reasonable age to stop screening.

Two studies evaluated the age to stop colonoscopy screening in the light of previous screening history, background risk, and comorbidity (van Hees et al., 2014a, 2015). The study by van Hees et al. compared the balance between benefits and harms of screening in elderly individuals for unscreened cohorts of people with and
without comorbidities (van Hees et al., 2014a). For these individuals, the benefits of screening at a later age are much greater than those for previously screened individuals, whereas the harms are relatively similar. Consequently, the modelling suggested that individuals without previous screening can be screened until a much later age and may still have a favourable balance between benefits and harms: up to age 83 years, 80 years, and 77 years for no, moderate, and severe comorbidities, respectively. Ideally, the age at which to stop screening should be based on personal risk, previous screening history, and comorbidity (van Hees et al., 2015). The current recommendation of continuing screening up to age 75 years could result in a loss, rather than a gain, of QALYs in some populations at low risk (e.g. for White women aged 74 years with moderate comorbidities, half the average background risk of CRC, and negative findings from a screening colonoscopy 10 years previously). For other groups, continuing screening was found to be highly cost-effective (e.g. for Black men aged 81 years with no comorbidities, an average background risk of CRC, and no previous screening). According to this study, the optimal age at which to stop screening varies between 66 years and 88 years, depending on individual risk, comorbidity, and previous screening history.

(iii) Screening interval

In the decision analysis for the USPSTF, the CISNET models also addressed the optimal interval for CRC screening (Knudsen et al., 2016). Two of the three models suggested that colonoscopy screening with a 15-year interval starting at age 45 years yielded a modest increase in life years gained and had a more favourable balance between life years gained and the clinical burden of colonoscopies, compared with colonoscopy every 10 years from age 50 years, without increasing the lifetime number of colonoscopies. However, one model estimated a slight loss in life years gained with this longer screening interval. Sigmoidoscopy screening was not found to be a sufficiently effective strategy compared with colonoscopy screening, and therefore no optimal interval was identified for this modality.

Six cost–effectiveness analyses also addressed endoscopy screening at different intervals, often comparing a single endoscopy, endoscopy every 10 years, and/or endoscopy every 5 years. One study even assessed a 3-yearly interval for colonoscopy (Table 3.3.18). The outcomes of the analyses varied widely, and no conclusions could be drawn about the optimal interval for endoscopy screening on the basis of these studies.
Table 3.3.18 Cost–effectiveness studies assessing different intervals for endoscopy screening

3.4 Comparison of the preventive effects of endoscopic methods and stool-based tests for blood

To date, only two methods have been assessed in RCTs to investigate reductions in CRC incidence or mortality: gFOBT and sigmoidoscopy. This section deals with comparisons between major endoscopic and stool-based CRC screening methods (i.e. sigmoidoscopy or colonoscopy vs gFOBT or FIT) in terms of mortality or incidence outcomes, ADRs, and cost-effectiveness. Comparisons of the established screening methods (colonoscopy, sigmoidoscopy, gFOBT, and FIT) in terms of participation are described in Section 3.6.

3.4.1 Reduction in colorectal cancer incidence or mortality

No RCT is available that directly compares two or more CRC screening tests. Evidence comes from indirect comparisons of observational studies and from indirect meta-analyses, so-called network meta-analyses using Bayesian statistics. Results from network meta-analyses are considered here, in the absence of direct comparison studies. [The Working Group highlighted as weaknesses of network meta-analyses the risk of non-comparability of control groups, the different screening participation rates across trials, and the heterogeneity in study designs available for the different screening methods compared (i.e. no trials available for colonoscopy or FIT). In conclusion, results from these studies were interpreted as lower-quality evidence.]

Of the five network meta-analyses identified, two focused exclusively on RCTs and thus included only gFOBT and sigmoidoscopy (Holme et al., 2013; updated by Emilsson et al., 2017), whereas the remaining three included observational studies as well but acknowledged that comparative estimates may be biased towards superiority of colonoscopy (Brenner et al., 2014; Elmunzer et al., 2015; Zhang et al., 2017).

The meta-analysis by Emilsson et al. (2017) included nine RCTs with 338 467 individuals randomized to screening and 405 919 individuals randomized to the control groups (Table 3.4.1). An indirect comparison of the primary analyses showed that sigmoidoscopy was superior to gFOBT in reducing CRC incidence (RR, 0.84; 95% predictive interval [PrI], 0.72–0.97). For CRC mortality, the relative risk for sigmoidoscopy versus gFOBT was 0.89 (95% PrI, 0.68–1.17). No heterogeneity was observed among the sigmoidoscopy trials, and moderate heterogeneity was reported among the gFOBT trials ($I^2 = 51.5\%$).

The remaining meta-analyses conducted indirect comparisons including both RCTs and observational studies. [Brenner et al. (2014) and Zhang et al. (2017) did not perform analyses restricted to studies in CRC screening settings as opposed to clinical settings, and therefore these network meta-analyses are not included in this evaluation.] With analyses restricted to studies in a screening setting, Elmunzer et al. (2015) reported improved effectiveness of colonoscopy in reducing CRC mortality compared with both sigmoidoscopy (RR, 0.56; 95% CI, 0.32–0.94) and gFOBT (RR, 0.49; 95% CI, 0.30–0.76). [There was significant heterogeneity among the studies included. However, when outlier studies were removed, the results were strengthened.]

3.4.2 Detection rates of adenoma and colorectal cancer

(a) Meta-analyses

Hassan et al. (2012) assessed participation in screening and compared the detection rates of advanced neoplasia between endoscopic methods and stool-based tests for blood, as well as within stool-based tests for blood (gFOBT vs FIT). Littlejohn et al. (2012) compared sigmoidoscopy either with no screening (not reported

CI, confidence interval; CRC, colorectal cancer; FIT, faecal immunochemical test; FS, flexible sigmoidoscopy; gFOBT, guaiac faecal occult blood test; ITT, intention-to-treat; PrI, predictive interval; RCTs, randomized controlled trials; RR, relative risk; vs, versus; yr, year or years.
here) or with alternative screening methods. All individual studies included in these meta-analyses are summarized in Table 3.4.2.

Both meta-analyses included RCTs or controlled studies, and they overlapped in seven studies (Berry et al., 1997; Verne et al., 1998; Rasmussen et al., 1999; Segnan et al., 2005, 2007; Multicentre Australian Colorectal-neoplasia Screening (MACS) Group, 2006; Hol et al., 2010).

The meta-analysis by Hassan et al. (2012) included several comparisons of screening methods in relation to detection of advanced neoplasia, advanced adenoma, and CRC. The study found that endoscopic techniques (sigmoidoscopy and colonoscopy) were more likely than stool-based tests for blood (gFOBT or FIT) to detect advanced neoplasia (RR, 3.21; 95% CI, 2.38–4.32) and CRC (RR, 1.58; 95% CI, 0.97–2.56). Separately, the detection rates of advanced neoplasia with both colonoscopy (RR, 3.56; 95% CI, 1.79–7.09) and sigmoidoscopy (RR, 3.2; 95% CI, 1.87–5.19) were significantly higher than those with gFOBT or FIT, whereas no significant differences were observed for the detection rates of CRC.

Littlejohn et al. (2012) included six studies that compared sigmoidoscopy with FOBT for the detection of advanced adenoma. Sigmoidoscopy (alone or in combination with FOBT) was more effective than FOBT alone in detecting advanced adenoma (sigmoidoscopy vs gFOBT: RR, 7.23; 95% CI, 4.86–10.75, comparing 4 studies; sigmoidoscopy vs FIT: RR, 3.74; 95% CI, 3.03–4.62, comparing 3 studies). Similar results were observed for the detection of CRC with sigmoidoscopy (alone or in combination with gFOBT) compared with gFOBT alone (RR, 3.34; 95% CI, 1.70–6.54) and with sigmoidoscopy (alone or in combination with FIT) compared with FIT alone (RR, 1.63; 95% CI, 0.67–3.97). [The Working Group noted that these comparisons were based on a small number of cases, and that the associations were weaker or non-significant for the CRC end-point.]

(b) Additional RCTs

Several additional RCTs published after 2012 have reported on the detection rates of advanced neoplasia, advanced adenoma, and/or CRC, comparing different screening modalities (see Table 3.4.2; Castells et al., 2014; Holme et al., 2014; Sali et al., 2016).

In a subanalysis of the population-based COLONPREV trial in Spain, which used FIT and colonoscopy in two study arms, the authors used the information from the colonoscopy up to the splenic flexure and interpreted it as sigmoidoscopy, with the aim of assessing how many colonic lesions sigmoidoscopy could detect. [The Working Group noted the possible limitation of simulating sigmoidoscopy by extrapolating from the colonoscopy results.] Simulated sigmoidoscopy was better than one-time FIT in detecting distal neoplasia (OR, 2.61; 95% CI, 2.20–3.10). Also, FIT and sigmoidoscopy did not differ significantly in their performance in detecting advanced proximal neoplasia (OR, 1.17; 95% CI, 0.78–1.76) (Castells et al., 2014).

In a trial in Norway of about 100,000 people, comparing sigmoidoscopy (n = 10,283) and the combination of FIT and sigmoidoscopy (n = 10,289), the detection rates of advanced adenoma and CRC were similar for the two modalities: the detection rates of advanced adenoma increased by 4.6% with sigmoidoscopy versus no screening and by 4.5% with combined FIT and sigmoidoscopy versus no screening, and the detection rate of CRC increased by 0.3% in both groups (Holme et al., 2014).

In a study of 9288 and 1036 residents of Florence, Italy, aged 54–65 years invited to participate in a CRC screening RCT with FIT or colonoscopy, respectively, Sali et al. (2016) reported that the detection rates of advanced neoplasia were 1.7% with first-round FIT and 7.2% with colonoscopy. The same study reported that colonoscopy was almost 5 times as likely as FIT to detect advanced neoplasia, in a model adjusted...

3.4.3 Cost–effectiveness

In recent years, many modelling studies (some of them conducted as part of national or international practice guideline projects) have evaluated the effectiveness of different CRC screening methods. Many of these modelling studies investigated more than one screening method or strategy. For a detailed overview of the studies on cost–effectiveness, see Section 3.2.6 and Section 3.3.6. Of the three systematic reviews of cost–effectiveness analyses of CRC screening, the most recent review by Patel & Kilgore (2015) was the only one to systematically compare all combinations of screening tests. That review included nine simulations that directly compared the costs (in United States dollars) and LYG of 10-yearly colonoscopy with those of annual gFOBT screening (Table 3.4.3). In all of the simulations, colonoscopy was more effective than annual gFOBT, and in most (six of nine simulations) the additional costs were less than US$ 50 000 per LYG. Five simulations compared 10-yearly colonoscopy versus annual HSgFOBT. In all five simulations colonoscopy was more effective than HSgFOBT and the additional costs were less than US$ 50 000 per LYG. For the comparison of 10-yearly colonoscopy versus annual FIT, the results were less consistent. In six of nine simulations, colonoscopy was more effective than FIT and more cost-effective with additional costs of less than US$ 50 000 per LYG, whereas in the other three simulations FIT was more effective and less costly than colonoscopy.

Comparisons of 5-yearly sigmoidoscopy versus annual HSgFOBT and FIT were very consistent, with 10 and 13 simulations, respectively, showing that sigmoidoscopy was less effective and more costly than these types of stool-based tests for blood. 5-Yearly sigmoidoscopy was consistently found to be more effective than annual gFOBT, and in most of the simulations, its additional costs were less than US$ 50 000 per LYG.

For the purpose of comparing different tests with a high degree of transparency with regard to the model applied, the most comprehensive and up-to-date study is part of the work developed for the latest update of the USPSTF recommendations for CRC screening, published in 2016 (Knudsen et al., 2016). This modelling study involved three microsimulation models – Simulation Model of Colorectal Cancer (SimCRC), Microsimulation Screening Analysis (MISCAN), and Colorectal Cancer Simulated Population Model for Incidence and Natural History (CRC-SPIN) – and used a hypothetical cohort of individuals aged 45, 50, or 55 years at the start of screening and aged 75, 80, or 85 years at the end of screening. A 100% participation rate in screening was assumed for all scenarios.

The following seven screening strategies were compared: HSgFOBT, FIT, the multitarget stool DNA (mt-sDNA) test, sigmoidoscopy (alone or in combination with stool-based testing for blood), computed tomography (CT) colonography, or colonoscopy. Different screening intervals and age ranges were explored. The primary end-point for all modelling analyses was LYG computed with the assumption that all gain from CRC detection would translate into LYG. The average LYG per 1000 people were 175–212 for HSgFOBT, 176–260 for FIT, 193–250 for mt-sDNA, 200–227 for sigmoidoscopy alone, 231–262 for sigmoidoscopy and FOBT, 184–265 for CT colonography, and 264–285 for colonoscopy. Although the ranges in LYG overlap for the different screening strategies, the models consistently found the highest LYG with 10-yearly colonoscopy, followed by the stool-based tests for blood, and the lowest LYG for sigmoidoscopy, which improved when sigmoidoscopy was combined with FOBT (Table 3.4.4).

3.5 Computed tomography colonography

3.5.1 Technique

The initial description of the use of computerized radiology for colon assessment dates back to the 1980s (Coin et al., 1983). However, it was not until more than a decade later that its full potential was better understood, because images to simulate the colon via three-dimensional (3D) fly-through techniques had been refined (Vining, 1996). The technology of computed tomography (CT) colonography enables a structural examination of the entire colon to be performed with a non-invasive method.

(a) Equipment

(i) Hardware

During the initial development of this technology, single-row helical CT scanners were used (Fenlon et al., 1999). Over time, the refinement of multidetector (or multirow) scanners has enabled the development of increasingly detailed images, and imaging times have become progressively shorter. For example, when a 64-slice multidetector scanner is used, the examination can be completed within a single breath hold of about 6–8 seconds (Lefere & Gryspeerdt, 2006). With multidetector scanners of at least 16 rows, submillimetre collimations are possible, enabling highly detailed 3D reconstructions (Cody & Mahesh, 2007).

Improvements in scanning technology continue. Currently, dual-source CT with 320 detector rows is in place at some centres. Automatic exposure control is also available (Kumar & Cash, 2017). This technology adjusts tube current continuously during the examination. Iterative reconstruction techniques are also being used. These improvements shorten the examination time and reduce radiation exposure. Nowadays, submillisievert examinations are possible (Lubner et al., 2015; Lambert et al., 2016).

(ii) Software

Software uses the cross-sectional image information obtained from the scanner to develop reconstructions of the colon for evaluation. Numerous developments in this area have enabled the image data to be manipulated in both two-dimensional (2D) and 3D formats (Kumar & Cash, 2017). Various types of 3D reconstructions are possible to facilitate reading. Examples of 3D reconstruction modes are fly-through, unfolded cube, and virtual dissection. The fly-through view develops colonoscopy-like images that can be examined in both antegrade and retrograde fashion, but it tends to have examination blind spots. Other reconstructions, such as unfolded cube and virtual dissection, “flatten” the colon more effectively and remove blind spots, but they introduce some distortion.

Data storage for the images can be a challenge. The use of a picture archiving and communication system (PACS) can facilitate both the storage and the retrieval of images when comparing examinations performed at different times and/or in separate venues.

(b) Procedure

From the patient perspective, there are several important considerations to ensure the completion of a high-quality examination. For example, the colon needs to be prepared before the examination and distended during the examination. Some of the key elements to patient preparation are discussed here.

(i) Colon preparation

As is the case for colonoscopy, the performance of CT colonography relies on adequate colon preparation to clear the colon of residual stool. Generally, dietary restriction (i.e. low-fibre diet) for at least a 24-hour period before the examination is recommended (Woodbridge &
Laxatives are often used to induce catharsis, although they are not mandatory (see below). Multiple laxatives are available for colon preparation. The polyethylene glycol preparations that are commonly used for colonoscopy are the safest, because they are least associated with fluid shifts and electrolyte imbalance (Neri et al., 2013b). However, a relative disadvantage of polyethylene glycol is the high-volume “wet” nature of the preparation. This can lead to retained fluid in the bowel (Macari et al., 2001), which can be easily suctioned during conventional colonoscopy but not effectively managed with CT colonography. For this reason, lower-volume preparations are often used (Laghi, 2014). This includes the use of osmotically active compounds such as sodium phosphate and magnesium citrate; however, some toxicity concerns remain about the administration of these types of agents in frail or elderly individuals. Acute phosphate nephropathy and the deposition of calcium phosphate within the renal tubules are particular concerns with sodium phosphate (Markowitz et al., 2005). A separate consideration in colon preparation is faecal tagging, which uses the ingestion of high-density contrast agents to differentiate residual colonic contents from polyps. Tagging improves specificity by enabling the digital subtraction of stool after image collection, to better highlight colonic polyps (Fletcher et al., 2013). Barium and iodine-based agents (ionic and non-ionic), either alone or in combination, have been used for this purpose. When a contrast agent is used, the patient is asked to ingest the agent with each meal the day before the CT colonography examination (Neri et al., 2013b). Importantly, the iodine-based agents are hyperosmolar and therefore have inherent cathartic effects. These agents have facilitated the development of colon preparation protocols with a reduced dose of a conventional cathartic agent (Lefere et al., 2002) or even without such an agent (Zalis et al., 2012; Zueco Zueco et al., 2012). Although the European Society of Gastrointestinal and Abdominal Radiology (ESGAR) consensus statement favours the use of faecal tagging (Neri et al., 2013a), there is no clear consensus about which agent to use. The American College of Radiology (ACR) also endorses tagging, recommending the use of soluble contrast, alone or combined with low-volume barium (American College of Radiology, 2014).

Adequate distension of the colon is a requirement for CT colonography. To accomplish this, the physician or technician performing the procedure inserts a small, flexible catheter. Options for insufflation of the colon include air and carbon dioxide. Carbon dioxide is absorbed through the bowel wall and exhaled, making overdistension and discomfort less likely. Carbon dioxide has been shown to be more effective in reducing abdominal pain, both for CT colonography (Shinners et al., 2006) and for colonoscopy (Memon et al., 2016).

(ii) Patient positioning

Generally, images are obtained in both the supine and the prone positions. Imaging in two positions has several advantages: it enables redistribution of fluid and stool and improves segmental distension (Tewari et al., 2013).

(iii) Image interpretation

There is no consensus about the best approach to image interpretation and whether starting with the 2D or 3D images affects the findings. Generally, a 2D read is considered to be faster than a primary 3D read (de Haan et al., 2015). The performance of the two approaches has been compared. A large study by Pickhardt et al. (2007a) demonstrated that for the detection of adenomas 6 mm or larger, primary 2D CT colonography was less sensitive (44.1%) than 3D CT colonography (85.7%). However, in the large (n = 2600) ACR Imaging Network (ACRIN) study, no significant difference was seen between the two approaches in the detection of large lesions (Johnson et al., 2007a).
The ESGAR consensus statement included statements about this topic (Neri et al., 2013a). There was strong consensus that interpretation should include both 2D and 3D visualization, and that the choice of the primary approach should be based on factors such as personal preference.

The time it takes to read a scan varies greatly, depending on experience and technique. In the multicentre study by Pickhardt et al. (2003), reading times were, on average, about 20 minutes. In a large, multicentre European investigation, somewhat shorter interpretation times were observed (~14 minutes) (Burling et al., 2006). The technique used is an important factor here. Although the 2D images have shorter interpretation times, there are multiple 3D approaches, which can vary in terms of time required for evaluation.

A separate but related issue for reading times is the use of a second reader to evaluate the scans. Computer-aided detection may facilitate the reading process; it uses software algorithms to highlight potential abnormalities that can be reviewed by the radiologists (Kumar & Cash, 2017).

A standard reporting format for CT colonography is now available. The CT Colonography Reporting and Data System (C-RADS) (Zalis et al., 2005) places studies into one of five categories of findings (C0–C4), depending on the interpretability of the scan and the severity of the findings. The categorization also outlines a suggested follow-up for each category. For findings in the categories C2 (intermediate polyp or indeterminate finding) and C3 (polyp, possibly advanced adenoma), colonoscopy is often the follow-up recommendation, and ideally systems are in place to move the patient to colonoscopy on the same day, so that a separate colon preparation is not required (Pickhardt, 2005). In addition to standard reporting of target findings within the colon, the C-RADS document also outlines standard reporting for extracolonic findings using a similar system of five categories (E0–E4).

(c) Quality control, including training

There is no single national or international standard on the performance of CT colonography. ACR (American College of Radiology, 2014) and ESGAR (Neri et al., 2013a) have issued guidance statements that cover the practical application issues discussed above.

The ACR document includes statements that preparation and distension should be adequate to detect large (≥ 10 mm) polyps, and that the examination should be a complete anatomical coverage (colon and rectum), with luminal surface views of each segment of the colon. The determination of detection rates for polyps 10 mm or larger is encouraged, as is the use of a registry to track performance. Guidance about interpretation includes outlining the need to have access to both 2D and 3D representations of the bowel, and to report polyp measurement in the largest dimension. ACR endorses the reporting of all polyps 6 mm or larger, and considers that reporting polyps smaller than 6 mm is not necessary. Significant extracolonic findings should be reported, and a “balanced approach” should be taken to recommending further workup of extracolonic findings, considering a host of factors (e.g. the clinical importance of the finding, cost, and patient anxiety) (American College of Radiology, 2014).

The approach of ESGAR to developing recommendations is slightly different to that of ACR. A panel of nine delegates from six European Union countries used a modified Delphi process to establish consensus. The panel was asked to evaluate 86 statements about all aspects of the CT colonography procedure, including patient preparation, image acquisition, and interpretation. After four rounds, the panel reached full consensus on 82% of the statements (Neri et al., 2013a).

The ACR document also establishes some training parameters for CT colonography. For physicians with prior qualifications in reading
abdominal and pelvic CT scans, education and hands-on experience with at least 50 CT cases is generally recommended. For physicians without prior experience in interpreting abdominal and pelvic CT scans (e.g. non-radiologists, such as gastroenterologists), completion of more than 200 hours of continuing medical education in the performance and interpretation of abdominal and pelvic CT scans and supervised review of at least 500 CT cases are needed before addressing CT colonography-specific training (American College of Radiology, 2014).

The American Gastroenterological Association released its own set of standards for gastroenterologists performing CT colonography (Cash et al., 2011). The guidance suggests that non-radiologists could perform colon-only interpretation (i.e. avoiding extracolonic CT images) after a period of fairly extensive training including more than 200 case reads with close mentorship.

(d) Screening performance

Several meta-analyses and systematic reviews have been conducted on the screening performance of CT colonography in terms of sensitivity and specificity (Mulhall et al., 2005; Whitlock et al., 2008; Martín-López et al., 2011; Pickhardt et al., 2011; Martín-López et al., 2014).

Most recently, the USPSTF performed a detailed evidence review (Lin et al., 2016a,b). Nine studies (Pickhardt et al., 2003; Macari et al., 2004; Johnson et al., 2007, 2008; Kim et al., 2008; Graser et al., 2009; Zalis et al., 2012; Fletcher et al., 2013; Lefere et al., 2013) of fair or good quality (n = 6497) assessed the screening performance of CT colonography. In seven studies (Pickhardt et al., 2003; Macari et al., 2004; Johnson et al., 2007, 2008; Kim et al., 2008; Graser et al., 2009; Lefere et al., 2013) colon preparation was used, and in two studies (Zalis et al., 2012; Fletcher et al., 2013) it was not. Colonoscopy was the standard reference for the assessment of test characteristics. When the seven studies that used colon preparation were considered, the per-person sensitivity of CT colonography for lesions 10 mm or larger was 67–94% and the per-person specificity was 96–98%. When lesions 6 mm or larger were considered, the per-person sensitivity was 73–98% and the per-person specificity was 89–91%.

An earlier meta-analysis also summarized evidence on the sensitivity of CT colonography for the detection of polyps (de Haan et al., 2011). It included four studies (Pickhardt et al., 2003; Johnson et al., 2008; Kim et al., 2008; Graser et al., 2009) that reported the sensitivity of CT colonography for adenoma detection at the 6 mm threshold and the 10 mm threshold. The per-patient sensitivity of CT colonography was 82.9% for adenomas 6 mm or larger and 87.9% for adenomas 10 mm or larger. No cancers were missed in any of these studies.

(e) Host factors that affect performance

Although there are several contraindications to the performance of CT colonography, most are not relevant to screening examinations. For example, there is an increased risk of perforation with CT colonography in those who have had recent colonoscopy or deep mucosal biopsies (American College of Radiology, 2014) (see also Section 3.5.3). One patient-related factor of some concern may be obesity. Radiological imaging generally requires higher doses of radiation in such circumstances (Yanch et al., 2009), and therefore the risk of inducing secondary cancer may be incrementally higher in obese individuals.

3.5.2 Preventive effects

There are no RCTs or observational studies that have reported CRC incidence or mortality outcomes associated with screening with CT colonography. Early evaluation of the effectiveness of CT colonography for the detection of advanced neoplasia was typically measured by tandem studies of CT colonography and colonoscopy in
a single group of patients (i.e. one-time screening with CT colonography followed by colonoscopy as the reference standard). These studies often included both asymptomatic individuals and individuals at higher risk (because of symptoms, family history, or history of colonic lesions), and therefore could not be interpreted as providing evidence related to test performance in a screening cohort.

Current evidence of the effectiveness of CT colonography comes from tandem studies, RCTs, and modelling studies in which detection rates of adenomas and cancer with CT colonography are compared with those with an established CRC screening test.

(a) **Tandem studies**

The tandem studies of CT colonography screening in asymptomatic adults in which the ADR and cancer detection rate (CDR) were reported or could be calculated are presented in Table 3.5.1. In 2003, Pickhardt et al. (2003) evaluated a cohort of 1233 asymptomatic adults who underwent same-day CT colonography and colonoscopy and observed slightly better performance with CT colonography in the detection rate of adenomas 10 mm or larger and of cancer compared with colonoscopy. The ADR for colonoscopy was superior to that for CT colonography for adenomas 6 mm or larger, but this was principally due to the subset of adenomas 6 mm in size. Kim et al. (2007) compared the performance of CT colonography and colonoscopy in two separate groups of consecutive adults undergoing screening with each test and observed similar detection rates for advanced neoplasia.

The first prospective, tandem study of significant size comparing CT colonography and colonoscopy in asymptomatic adults was the National CT Colonography Trial (ACRIN 6664), reported in 2008 (Johnson et al., 2008). The trial recruited about 2600 asymptomatic adults 50 years or older who underwent CT colonography followed by colonoscopy, which served as the reference standard. The primary end-point was detection by colonoscopy of large adenomas (≥ 10 mm) and adenocarcinomas, although radiologists reported all detected lesions 5 mm or larger, which enabled comparative measures of sensitivity per millimetre of size of adenomas and cancers. Per-polyp sensitivity was expressed as the proportion of lesions detected by colonoscopy that were also detected by CT colonography, which increased with increasing lesion size, from 0.59 for polyps 5 mm or larger to 0.84 for polyps 10 mm or larger (Johnson et al., 2008). Separate per-patient ADR and CDR were not reported. Graser et al. (2009) evaluated the performance of gFOBT, FIT, sigmoidoscopy, CT colonography, and colonoscopy in a group of 307 asymptomatic adults who underwent each of these tests consecutively, with colonoscopy as the reference standard. CT colonography and colonoscopy had a nearly equivalent performance in the detection of advanced adenomas (7.5% vs 8.1%) and of advanced neoplasia (9.4% vs 9.8%), and both CT colonography and colonoscopy identified the one case of cancer in the study group.

(b) **Randomized controlled trials**

In the Netherlands, the Colonoscopy or Colonography for Screening (COCOS) trial was initiated in 2009 to compare the participation rate and the detection rates between a CT colonography arm \((n = 982\) of 2920 CT colonography invitees) and a colonoscopy arm \((n = 1276\) of 5924 colonoscopy invitees) and to eventually link participants to the national cancer registry 10 years after invitation, for follow-up on CRC incidence and mortality (de Wijkerslooth et al., 2010; Stoop et al., 2012). Participants in the CT colonography arm who had one or more lesions 10 mm or larger were offered immediate colonoscopy; participants with three or more lesions 6–9 mm were scheduled for colonoscopy in 1.5 years, and participants with one to two lesions of 6–9 mm were offered surveillance CT colonography in 3 years. The two primary outcomes were...

the participation rate, defined as the number of invitees undergoing the examination relative to the total number of invitees, and the detection rate, defined as the number of participants with advanced neoplasia relative to the total number of invitees. The CDR per 100 participants was equivalent in the CT colonography and colonoscopy arms (both 0.5%; \( P = 0.91 \)), and the CDR per 100 invitees was 0.1 in the CT colonography arm and 0.2 in the colonoscopy arm (\( P = 0.50 \)). The overall advanced ADR per 100 participants was higher in the colonoscopy arm (8.2%) than in the CT colonography arm (5.6%) (\( P = 0.02 \)), and the advanced ADR per 100 participants for adenomas 10 mm or larger was also higher in the colonoscopy arm (6.3%) than in the CT colonography arm (5.4%), although the difference was not statistically significant (Stoop et al., 2012). [Because enrolment was considerably lower than initial targets, the Working Group expressed concerns that the study had insufficient statistical power.]

Two RCTs in Italy compared the detection rate and the participation rate between CT colonography and other CRC screening methods. The SAVE trial randomized adults to CT colonography, FIT, and colonoscopy to compare the participation rate, detection rate, and screening costs (Sali et al., 2013, 2016). A cohort of approximately 16 000 adults aged 54–65 years with no history of CRC screening was randomized into three groups. Group 1 (\( n = 1286 \) of 4825 eligible invitees) was invited to undergo CT colonography, and the CT arm was divided into reduced cathartic preparation and full cathartic preparation groups. Group 2 (\( n = 4677 \) of 9288 eligible invitees) was invited to undergo three rounds of biennial FIT. Group 3 (\( n = 153 \) of 1036 eligible invitees) was invited to undergo colonoscopy. Adults in the CT colonography arm with one or more polyps 6 mm or larger or with a colonic mass were invited to undergo colonoscopy, and adults with no lesions or with polyps smaller than 6 mm were classified as having negative results and were invited to undergo FOBT after 5 years. The advanced ADR was 4.7% in the CT colonography arm versus 7.2% in the colonoscopy arm, and the detection rate for all advanced neoplasia was 5.2% in the CT colonography arm versus 7.2% in the colonoscopy arm. [The investigators considered the smaller size of the colonoscopy arm (\( n = 153 \)) as a limitation of the study and emphasized that the principal interest in comparing the CT colonography arm (\( n = 1286 \)) and the colonoscopy arm related to participation rate and not detection rate.] CT colonography detected more CRC compared with FIT (0.5% vs 0.1%) and more advanced adenomas (4.7% vs 1.6%) per participant (Sali et al., 2016). [The Working Group noted the difference in the size of the arms as a limitation.]

The second RCT in Italy, the Proteus trial, included two RCTs comparing the acceptability and detection rate between CT colonography and sigmoidoscopy within a population-based screening programme: a pragmatic RCT comparing participation rates (Proteus 1) and an efficacy RCT comparing advanced ADR and CDR (Proteus 2) (Regge et al., 2014, 2017). The target population comprised adults aged 58 years residing in the Piedmont region and adults aged 60 years residing in Verona. Adults who agreed to participate were randomized to either sigmoidoscopy or CT colonography with non-cathartic preparation. Participants in the CT colonography arm with no lesions or with lesions smaller than 6 mm were interpreted as having negative results; participants with lesions 6 mm or larger were referred for colonoscopy. In the sigmoidoscopy arm, polyps smaller than 10 mm detected during sigmoidoscopy were removed and sent for histological evaluation, and participants with polyps 10 mm or larger or with “high-risk polyps” (at least one advanced adenoma < 10 mm, or more than two small tubular adenomas with low-grade dysplasia) were referred for colonoscopy. In Proteus 2, comparable CDRs and ADRs were
reported for CT colonography and sigmoidoscopy. The CDR was 0.4% for CT colonography and 0.3% for sigmoidoscopy, and the advanced ADR for lesions 10 mm or larger was 3.8% for CT colonography and 3.5% for sigmoidoscopy. The detection rate for proximal advanced neoplasia for CT colonography (2.7%) was double that for sigmoidoscopy (1.3%); the detection rate for distal advanced neoplasia was 2.9% for CT colonography and 4.1% for sigmoidoscopy. [The investigators speculated that quality issues, such as the non-cathartic preparation, suboptimal distension, and a new computer-aided detection reading algorithm, may have contributed to the lower than expected detection rates in the distal colon (Regge et al., 2017).]

(c) Modelling studies

Simulation modelling of different screening strategies provides an opportunity to estimate their comparative effectiveness and to estimate conventional end-points such as CRC incidence, mortality, and LYG associated with screening.

Lucidarme et al. (2012) used a simulation model to assess the outcomes and cost-effectiveness of colonoscopy, CT colonography, and gFOBT (without rehydration) based on varying rates of attendance over a 10-year period. The screening intervals for colonoscopy, CT colonography, and gFOBT were 10 years, 5 years, and 2 years, respectively, with colonoscopy surveillance intervals of 3–5 years, depending on the nature of positive findings at screening. An unconventional, but practical, end-point was used: the rate of remaining CRC, defined either as screened and undetected disease or as unscreened and undetected disease (in keeping with simulated attendance rates), to estimate the cost per CRC avoided over 10 years. For example, with no screening, the remaining CRC rate per 10 000 people was estimated to be 123 cancers per 10 000 adults older than 50 years, equivalent to the expected cumulative incidence over the 10-year period. With 100% participation in screening, which represents one screening colonoscopy or two screening CT colonographies over the 10-year period, the model estimated that the remaining CRC rate per 10 000 adults was 17 in the colonoscopy arm and 2 in the CT colonography arm (Lucidarme et al., 2012). [The Working Group noted that in the CT colonography arm there were two opportunities to diagnose a CRC, compared with one opportunity in the colonoscopy arm, consistent with a 5-year screening interval for CT colonography compared with a 10-year screening interval for colonoscopy.] Overall, for any participation rate in the simulation, CT colonography screening was the most effective but not always the most cost-effective strategy; gFOBT was the least effective but most cost-effective strategy, and colonoscopy had an intermediate effectiveness and was the least cost-effective strategy (Lucidarme et al., 2012).

The Cancer Intervention and Surveillance Modeling Network (CISNET) recently estimated the long-term effectiveness of CT colonography for the USPSTF’s update of its 2008 CRC screening recommendations (Bibbins-Domingo et al., 2016); modelling conducted for the 2008 update did not include CT colonography (Zauber et al., 2008). The modelling was conducted with three separate microsimulation models (SimCRC, MISCAN, and CRC-SPIN) and was used to simulate the effects of different ages at the start of screening and the end of screening, and of different screening intervals, on life years lost and LYG as a measure of benefit, and the number of lifetime colonoscopies as a measure of the burden of screening for an individual aged 40 years at average risk beginning screening at various ages in the simulations (Knudsen et al., 2016). Screening strategies included annual HSgFOBT and FIT, mt-sDNA, sigmoidoscopy every 10 years with annual FOBT or sigmoidoscopy every 5 years without FOBT, CT colonography, and colonoscopy. In all three microsimulations, CT colonography test characteristics were derived from the ACRIN 6664 trial (Johnson et al., 2008). For
3.5.3 Adverse effects

The potential adverse effects of CT colonography include perforation, non-serious adverse events associated with colon preparation (such as abdominal pain), and examination-related pain, vasovagal syncope, and presyncope. Other potential harms are an increased risk of radiation-induced cancer from a single examination or multiple examinations, and extracolonic findings.

Perforation during CT colonography screening is very rare and is typically associated with insufflation. A common finding in most reports of perforation during CT colonography is the presence of symptoms such as inflammatory bowel disease, ulcerative colitis, and cancer. Lin et al. (2016a) identified 15 studies that addressed serious adverse events associated with CT colonography in screening and mixed populations (screening and diagnostic examination). The risk of perforation during CT colonography was less than 0.02% overall (2 per 10 000 CT colonography procedures); in 11 prospective studies restricted to screening populations (n = 10 272), no perforation events were reported (Lin et al., 2016a). In another systematic review and meta-analysis of 11 studies including more than 100 000 patients (including 7 among the 15 studies from Lin et al., 2016a), 28 colon perforations were reported, for an estimated perforation rate of 0.04% overall and 0.02% in asymptomatic patients (Bellini et al., 2014).

Although only low-dose, non-enhanced multidetector CT protocols are recommended for screening asymptomatic adults at average risk, there is still concern about the estimated risk of radiation-induced cancer from a single examination and multiple examinations, and the cumulative dose that may be accrued from examinations for other conditions (Brenner & Hall, 2007). The systematic review by Lin et al. (2016a) of CT colonography screening studies revealed few studies that reported average exposures and
dose levels, but the evidence reflected a decrease in exposures over time with newer multidetector scanners and greater attention to dose-reducing protocols. For example, in the ACRIN 6664 study, which enrolled participants in 2005–2006, the estimated mean effective dose per CT colonography screening study was 8 mSv for women and 7 mSv for men, whereas more recent data from a 2011 survey of practices in the USA revealed that the mean effective radiation dose for CT colonography screening had declined to 4.4 mSv (Boellaard et al., 2012). This effective dose level is greater than that of a chest X-ray (0.4 mSv) and a mammogram (0.4 mSv) but less than that of most diagnostic CT procedures (American College of Radiology, 2017) and is estimated to be equivalent to about 16 months of natural background radiation.

Berrington de González et al. (2011) estimated the radiation-related risk of cancer using risk projection models based on the report of the Biological Effects of Ionizing Radiation (BEIR) VII committee (Committee to Assess Health Risks from Exposure to Low Levels of Ionizing Radiation, 2006) and screening protocols from the ACRIN 6664 trial (Berrington de González et al., 2011). A single CT colonography examination at age 50 years would result in a slightly higher risk (0.06%) than a single screening examination at age 70 years (0.03%). A series of CT colonography examinations every 5 years from age 50–80 years, which include additional radiation exposure from follow-up CT examinations for incidental, extracolonic findings, were estimated to result in a 0.15% risk of radiation-induced cancer (Berrington de González et al., 2011). The estimated benefit of screening in avoiding a CRC death was estimated to be considerably higher than the estimated risk of radiation-induced death from CRC screening, with a ratio ranging from 35:1 to 47:1 (Berrington de González et al., 2011).

Extracolonic findings represent potential harms, but in some instances the detection of an extracolonic finding may be beneficial. Extracolonic findings were reported in 27–69% of CT colonography examinations (Lin et al., 2016a) and included small masses, suspected cancers, aneurysms, and adenopathy. Detection of unsuspected, clinically significant findings, such as extracolonic cancers, which are uncommon, and abdominal aortic aneurysms, may represent a benefit to the patient. However, some extracolonic findings may be insignificant, requiring no further evaluation, whereas others are judged to be potentially serious enough to warrant additional imaging, which may prove to be unproductive and result in an increased radiation dose and in diagnostic and therapeutic procedures that may also result in serious complications. On the C-RADS scale ranging from E0 to E4 (where E0 is a compromised examination and E1 or E2 represents no or insignificant extracolonic findings), E3 is judged as likely unimportant but may warrant additional workup, and E4 is a potentially important finding that requires follow-up (Zalis et al., 2005).

Lin et al. (2016a) summarized the challenges of obtaining clear estimates of the burden of extracolonic findings from studies that often include heterogeneous patient samples (asymptomatic vs mixed populations), variations in reporting extracolonic findings (all vs suspected malignancies only), variable age ranges in the study group (the risk of extracolonic findings increases with age), variations in reporting medical follow-up including treatment, and variations in duration and completeness of follow-up. In a review of 21 studies ranging in size from 75 patients to 10,286 patients, Lin et al. (2016a) reported that the frequency of E3 and E4 findings ranged from 5% to 37%, and the frequency of E4 findings ranged from 1.7% to 12%. In studies that reported medical follow-up, 1.4–11% of patients were referred for further evaluation, but only 3% or less underwent treatment. In a report from a large single practice (Pooler et al., 2016), 88.3% of the patients with extracolonic findings had
category E1 and E2 extracolonic findings (not clinically relevant), 9.1% had E3 findings (likely unimportant), and 2.5% had E4 findings (potentially important). The potential benefit of extracolonic findings was higher in the E4 group, with 68% of patients receiving a diagnosis of clinically significant disease (malignancies, abdominal aortic aneurysms, etc.), whereas patients with an E3 finding were very unlikely to have clinically significant extracolonic disease (8.3%).

3.5.4 Benefit–harm ratio and cost–effectiveness

The benefits of CT colonography include high sensitivity for advanced adenomas and cancer, and the possibility that some extracolonic findings represent important occult disease. Harms associated with CT colonography include perforation (for which the risk is lower than that with colonoscopy), radiation-induced cancer, the need to undergo a second colon preparation if the findings are positive and same-day colonoscopy is not feasible, and the downstream effects of the detection of extracolonic findings that warrant further investigation and are determined to be benign. The existing evidence indicates that CT colonography has a favourable benefit–harm ratio.

The cost–effectiveness of CT colonography can be estimated relative to no screening or relative to other screening tests (de Haan et al., 2015). The costs of CT colonography include costs associated with the initial examination, costs associated with follow-up colonoscopy, and costs associated with the evaluation and treatment of extracolonic findings. The review of the studies of cost–effectiveness of CT colonography relative to no screening found that in all studies CT colonography screening, at different intervals, was cost-effective relative to no screening (de Haan et al., 2013). Knudsen et al. (2010) also estimated that CT colonography screening every 5 years was cost-beneficial (i.e. less costly) relative to no screening in the Medicare population in the USA, and Heresbach et al. (2010) showed that CT colonography screening easily meets conventional criteria for cost–effectiveness compared with no screening.

Comparative cost–effectiveness, when CT colonography is compared with other screening tests, is sensitive to model parameters, i.e. the cost of the tests, additional programme costs, testing intervals, test accuracy, downstream costs, and assumptions about the natural history of the disease. Although model assumptions, including test performance, intervals, and participation rates, vary considerably in existing models, most comparisons have been with colonoscopy and have shown that colonoscopy every 10 years is more cost-effective than CT colonography is (Knudsen et al., 2010; Lee et al., 2010). However, cost–effectiveness is significantly influenced by the cost and the estimated accuracy of the tests being compared and, in particular, the participation rate. CT colonography has been shown to be more cost-effective than colonoscopy when the participation rate of CT colonography exceeds that of colonoscopy (Pickhardt et al., 2007b; Knudsen et al., 2010; Hassan & Pickhardt, 2013). For example, assuming 100% participation in screening in the Medicare population in the USA, Knudsen et al. (2010) showed that the LYG from 5-yearly CT colonography was similar to the LYG from 10-yearly colonoscopy but that the programme costs of CT colonography were higher. However, if the relative participation in CT colonography screening was 25% higher than participation in other tests, then CT colonography could be cost-effective if reimbursed at US$ 488 per examination (Knudsen et al. 2010).

In a recent simulation of CRC screening in the Netherlands, van der Meulen et al. (2018) compared the cost–effectiveness of CT colonography versus colonoscopy in a microsimulation model (MISCAN) using data from the COCOS trial. In the comparison of 10-yearly screening with colonoscopy and CT colonography in 1000
adults aged 50–70 years with 100% participation, screening with colonoscopy resulted in fewer CRC deaths and more QALYs gained (106 vs 81) compared with CT colonography. The costs of the colonoscopy programme were higher than those of the CT colonography programme, but treatment costs were lower, which resulted in lower total programme costs for colonoscopy. In contrast, when observed CT colonography participation rates from the COCOS trial were used, which were higher than colonoscopy participation rates, CT colonography screening had higher costs but was associated with a higher reduction in CRC deaths and more QALYs gained (29 vs 22). Based on observed participation rates, the simulation showed that colonoscopy screening with more than two lifetime screens would be less cost-effective than CT colonography screening.

3.6 Participation in screening for colorectal cancer

The conceptual frameworks that have been proposed to analyse factors that influence access to, delivery of, and quality of screening (Green & Kreuter, 2005; Anhang Price et al., 2010; Sabatino et al., 2012) acknowledge that screening is a process of care that occurs in a multilevel environment, including at the policy, organization, provider, and patient levels (Table 3.6.1). The delivery by providers and the use of screening by individuals are influenced by several factors that interact synergistically at these different levels of the health-care system.

3.6.1 Determinants of participation in colorectal cancer screening

(a) At the policy level

The type of insurance coverage and the cost of the test have been consistently shown to influence screening rates and subjects’ preferences for specific tests (Gimeno Garcia et al., 2014; May et al., 2017; White et al., 2017). Insurance status is the most important determinant of use of screening services in the USA, where screening is primarily opportunistic (Gellad & Provenzale, 2010). Also, co-payment [financial participation by the screenee] for a CRC screening test was found to be associated with lower screening rates among subjects with lower income (Fedewa et al., 2015). An analysis of temporal trends in CRC mortality before and after introduction of screening in the USA supports the hypothesis that screening rates are lower in populations with lower (uninsured) socioeconomic status (SES) than in populations with higher SES, and that this difference contributed to the observed widening of the disparity in population mortality (Breen et al., 2017).

Compared with areas where only opportunistic screening is available, higher screening rates have been reported and disparities by SES tended to be smaller in areas where organized programmes had been introduced (Eisinger et al., 2008; Carrozzi et al., 2015a). However, studies conducted within organized FOBT-based programmes (de Klerk et al., 2018) showed substantial differences in participation between the least deprived and the most deprived subjects, suggesting that lower SES may still be a barrier to screening participation even in organized settings. In settings where most CRC screening relies on office-based interventions delivered by primary care physicians, subjects without access to primary care are excluded from participation (Levin et al., 2011; White et al., 2017).

(b) At the organizational level

(i) Invitation

Organizational measures that enable subjects to adopt the recommended behaviours play a crucial role. Studies in opportunistic settings showed that delivering informational material was associated with an increase in screening rates only if providers offered support for scheduling screening appointments and subjects were not requested to make arrangements on their own (Costanza et al., 2007; Sequist et al., 2009). There is strong evidence that reminders (i.e. active invitations sent by mail to subjects who are due, or overdue, for CRC screening) are effective in increasing participation in screening (Sabatino et al., 2012; Camilloni et al., 2013). Other factors related to service organization that are consistently inversely related to participation in screening are the amount of time required to perform screening and the distance of the subject’s residence from the test provider (Jeppson et al., 2000; Federici et al., 2006a; Koo et al., 2012). Population-based programmes provide the organizational framework for reducing inequities in screening access by using call-and-recall systems, which ensure that each eligible subject has the opportunity to participate.

CRC, colorectal cancer; FIT, faecal immunochemical test; gFOBT, guaiac faecal occult blood test; GP, general practitioner; SES, socioeconomic status.

* Determinants are classified according to the framework of the Precede–Proceed model (Greene & Kreuter, 2005).

b Assessment conducted in opportunistic settings.

c Acceptability of the screening strategies is context-specific, and it may vary across jurisdictions. Assessment of participation should be one of the aims of pilot screening studies.
(ii) **Screening modality**

Multiple tests are currently used for CRC screening, and they have different effectiveness, acceptability, safety, and cost profiles. Dislike of the recommended test appears to be a specific barrier to participation in CRC screening (Lo et al., 2013).

Participation rates in programmes with stool-based tests for blood are higher in women than in men (Klabunde et al., 2015; Ponti et al., 2017), whereas participation rates in endoscopy-based programmes are higher in men than in women (Segnan et al., 2005; Ponti et al., 2017).

(c) **At the provider level**

The involvement of general practitioners (GPs) was shown to be effective in increasing participation in both organized programmes (Grazzini et al., 2000; Raine et al., 2016) and opportunistic settings (Seifert et al., 2008; Koo et al., 2012). Participation in screening was shown to be closely linked to the GP’s level of motivation for screening (Federici et al., 2006a) and to the level of support provided by other trusted primary care physicians (Malila et al., 2008), in particular for less-educated people or older people, who are less likely to use written informational material (Senore et al., 2010). However, some studies reported that these populations are less likely to receive advice about CRC screening from a GP or other primary care physician (Sabatino et al., 2008; Ferroni et al., 2012), which would suggest that inadequate GP counselling may contribute to the observed SES-related gradient in participation.

The lack of knowledge of primary care physicians about the effectiveness of recommended screening modalities and about test characteristics and screening protocols appears to be an important barrier to screening participation in several countries (Koo et al., 2012; Honein-AbouHaidar et al., 2016; Muliira et al., 2016). Enhancing health-care providers’ knowledge about CRC screening should increase participation in CRC screening. Other provider-associated barriers are failure to recall patients or to identify high-priority patients for screening, and lack of time dedicated to preventive care (Stone et al., 2002).

The characteristics of the provider may also play a role in participation rates. Women may perceive endoscopy examinations to be less embarrassing if they are conducted by a female endoscopist (Menees et al., 2005). The lack of a sex difference in participation rates when sigmoidoscopy screening was delivered by a female nurse (Robb et al., 2010) supports this hypothesis.

(d) **At the patient level**

Lack of awareness of CRC and of the purposes of CRC screening, and negative perceptions or attitudes (e.g. worry about pain, discomfort, embarrassment associated with the test, fear about test results, shyness about being screened, the perception that screening is not necessary, or fatalistic views of cancer) emerge as barriers to screening participation, in both qualitative and quantitative studies, and were consistently associated with a lower participation rate (Galal et al., 2016; Honein-AbouHaidar et al., 2016; Wools et al., 2016). Anxiety associated with regular repetition of screening tests was a strong negative predictor of participation in CRC screening, even among those who believed the screening to be effective (Senore et al., 2010).

Culture- and religion-specific barriers to screening participation may pose additional hurdles, independent of financial considerations, that limit participation in CRC screening. Subjects who hold traditional views of care tend to have lower screening participation, probably as a result of misconceptions about CRC and about screening, a distrust of conventional medicine, or a lack of familiarity with screening tests. Religious objections and cultural background, which may affect an individual’s perception of the acceptability of the test, have been reported as
barriers to participation in endoscopy screening (Galal et al., 2016; Honein-AbouHaidar et al., 2016; Taha et al., 2016).

Perceived susceptibility to CRC is a facilitator for participation in screening, although several studies have shown that perception of a high CRC risk may be associated with an increase in participation in endoscopy but not in FOBT (Wools et al., 2016). Health motivation, measured by either the adoption of health-promoting behaviours (e.g. undergoing mammography screening, having a cholesterol check, or visiting a GP or dentist) or the avoidance of unhealthy habits (e.g. smoking or alcohol consumption), has been identified as a factor that is associated with a higher likelihood of participating in CRC screening, although lower participation has been reported among individuals who reported a very healthy lifestyle (Sicsic & Franc, 2014).

The persistent differences in participation in CRC screening by SES, or education level, also in the context of established population-based programmes (de Klerk et al., 2018), may be partially explained by differences in knowledge, beliefs, and expectations (Honein-AbouHaidar et al., 2016; Smith et al., 2016): groups with lower SES may consider screening to be more frightening and less beneficial compared with groups with higher SES, even if screening is publicized in an identical way and is provided free of charge, at a convenient location and time, to all SES groups. Better self-rated health and lower cancer fatalism, which are directly associated with higher participation in FOBT screening, mediate the impact of SES on participation (Miles et al., 2011). Qualitative research findings indicate that cognitive factors, including fatalistic beliefs about CRC (Lo et al., 2013; Honein-AbouHaidar et al., 2016) and the individual’s perception of the relative weights of short-term inconveniences and long-term benefits (Whitaker et al., 2011), are associated with SES and mediate the negative impact of social deprivation on participation. Social cognition variables (i.e. knowledge, risk awareness, and attitudes) were shown to be strongly associated with intention but only weakly associated with action; action is better predicted by factors related to life difficulties (Power et al., 2008), which are likely to be associated with higher deprivation levels (Smith et al., 2016).

SES may also mediate the impact of ethnicity on participation: ethnic differences in screening participation tend to decrease (Liss & Baker, 2014), or even to disappear (Doubeni et al., 2010), after adjustment for level of knowledge, SES indicators, or access to care. Also, a screening survey in Italy showed a strong correlation between the participation rate of immigrants and that of Italians by screening programme, suggesting that some structural determinants of accessibility are common to different ethnicities (Turrin et al., 2015).

Studies in different countries reported a positive association between having a family history of CRC or having had direct experience of CRC affecting relatives or friends and the likelihood of responding to an invitation to CRC screening (Koo et al., 2012; Galal et al., 2016; Honein-AbouHaidar et al., 2016), although no such effect was observed in other studies.

Support from a partner plays a strong role: married adults are more likely than non-married adults to participate in CRC screening (Artama et al., 2016; Galal et al., 2016; Wools et al., 2016; Honein-AbouHaidar et al., 2016).

(e) Follow-up of subjects with abnormal findings

The potential reduction of mortality through screening can be achieved only if subjects with abnormal findings receive timely and appropriate follow-up, following evidence-based guidelines. According to reports from surveys monitoring the receipt of appropriate follow-up care by patients with abnormal results, a substantial proportion (8–34%) of subjects with positive
test results are not undergoing the recommended assessment (Yabroff et al., 2003; Ponti et al., 2017).

The following interventions have been found to be successful in increasing the proportion of screen-positive individuals who receive timely follow-up: reducing financial barriers to further investigations and providing reminders by mail or telephone; providing written informational material, telephone counselling, or face-to-face counselling; and addressing fears related to abnormal findings (Bastani et al., 2004; Zorzi et al., 2014).

3.6.2 Interventions to increase participation in endoscopy screening

Randomized trials of interventions to increase participation in endoscopy screening (colonoscopy or sigmoidoscopy) are presented in Table 3.6.2. Of the 11 trials found in the literature, seven were of colonoscopy, three were of sigmoidoscopy, and one was of either sigmoidoscopy or colonoscopy. Five of the trials were conducted in the USA and six in Europe. All of the trials in the USA (Denberg et al., 2006; Turner et al., 2008; Ling et al., 2009; Jandorf et al., 2013; Jensen et al., 2014) and two of the trials in Europe (Gray & Pennington, 2000; Boguradzka et al., 2014) assessed participation in the context of opportunistic screening. Of the other four trials in Europe, one assessed participation within a sigmoidoscopy screening trial (Wardle et al., 2003), two assessed participation in subjects identified from population registries (Senore et al., 1996; Blom et al., 2002), and one assessed participation in an organized population-based screening programme (Senore et al., 2015a).

Four trials evaluated patient navigation, management, coaching, or counselling versus a control arm of usual care or an informational brochure or leaflet (Turner et al., 2008; Ling et al., 2009; Jandorf et al., 2013; Boguradzka et al., 2014). Of these trials, two found significantly higher participation in the intervention arm than in the control arm (OR, 1.63; 95% CI, 1.11–2.41 and OR, 5.33; 95% CI, 3.55–8.00), one found an effect of borderline significance (OR, 2.14; 95% CI, 0.99–4.63), and one reported a non-significant effect. An additional trial evaluated different methods of having a patient interact with a nurse coordinator and found no significant difference (Blom et al., 2002).

Four trials evaluated the impact of invitation letters on participation rates (Senore et al., 1996; Ling et al., 2009; Jensen et al., 2014; Senore et al., 2015a). A 2 × 2 factorial study showed that participation was higher with a narrative invitation than with a non-narrative invitation (OR, 4.81; P < 0.05), but no significant difference was found for a tailored invitation versus a standard (stock) invitation (Jensen et al., 2014). Another study of a tailored invitation letter versus a non-tailored invitation letter also found no significant difference (Ling et al., 2009). A study of an advance notification letter versus usual care found significant differences (RR, 1.17; 95% CI, 1.10–1.25 and RR, 1.19; 95% CI, 1.12–1.27) (Senore et al., 2015a). A study of personal letters signed by a GP versus a study coordinator found no significant difference (Senore et al., 1996).

Two trials that examined providing an informational brochure versus usual care both found a significant difference, although it was of modest magnitude (Wardle et al., 2003; Denberg et al., 2006). One trial examined the addition of a discussion with the GP to providing an informational leaflet and found no significant difference (Gray & Pennington, 2000).

3.6.3 Interventions to increase participation in screening with stool-based tests for blood

More than 25 RCTs have assessed interventions to increase participation in gFOBT and/or FIT screening in asymptomatic individuals at average risk of CRC in high-income

countries (Australia, Israel, and countries in North America and western Europe). In view of the very large number of RCTs, the main focus of this section is on recent systematic reviews.

The most recent systematic review (Rat et al., 2017a) included RCTs published up to September 2015 (Table 3.6.3). The 24 RCTs that met the inclusion criteria were categorized according to whether the intervention focused on information provided to those invited to screening, physician practice, or type of test (i.e. gFOBT vs FIT). The interventions that increased participation in gFOBT and/or FIT screening were: advance notification letter (OR, 1.20–1.51); postal mailing of kits (OR, 1.31–2.89); written, telephone, and text message reminders (OR, 1.94–7.70); and telephone contact with an advisor (OR, 1.36–7.72). The interventions focused on physician practice that were effective were an invitation letter signed by a GP (OR, 1.26), GP training focused on communication skills (OR, 1.22), and reminder letters sent to GPs (OR, 14.8). For RCTs that compared gFOBT with FIT, the results were mixed.

In the USA, the Community Preventive Services Task Force published an update of its systematic review on the effectiveness of interventions to increase participation in cancer screening (Sabatino et al., 2012), based on published literature up to October 2008. Interventions were categorized as increasing community demand for screening, reducing barriers to access, and increasing screening service delivery by health-care providers. One-on-one education, client reminders, and reducing structural barriers were effective in increasing use of CRC screening.

The results of another systematic review (Senore et al., 2015b) indicated that multifactor interventions that target factors outside the control of individual clinicians are most effective in increasing participation in gFOBT and/or FIT. In organized CRC screening programmes (implying that there are no financial barriers to the potential participant), letters of invitation, especially if signed by the person’s GP, and reminder letters sent to non-participants were found to be effective in increasing participation. Physician reminders were also found to increase participation in screening.

A three-group cluster RCT (Rat et al., 2017b), completed after the most recent meta-analysis and conducted within the organized CRC screening programme in France, reported that providing GPs with a list of their patients who were not up to date with screening was associated with a small increase in the participation rate in FIT screening. At 1 year, the participation rate in screening was 24.8% (95% CI, 23.4–26.2%) in the group who received specific reminders, 21.7% (95% CI, 20.5–22.8%) in the group who received generic reminders, and 20.6% (95% CI, 19.3–21.8%) in the usual care group.

3.6.4 Comparison of participation in two screening methods

(a) Comparing stool-based tests for blood

A meta-analysis of seven informative comparative trials (Vart et al., 2012) reported a higher participation among people invited to FIT than among those invited to gFOBT (RR, 1.21; 95% CI, 1.09–1.33). Also, the adoption of FIT in some population-based programmes in the United Kingdom resulted in a reduction in the participation gap by age, sex, and deprivation level observed in the gFOBT-based programmes (Digby et al., 2013; Moss et al., 2017).

(b) Comparing endoscopic methods

In a trial in Italy (Segnan et al., 2007), participation was significantly lower among subjects invited to colonoscopy than among those invited to sigmoidoscopy screening (27% vs 32%; OR, 0.74; 95% CI, 0.68–0.80).

Two studies also assessed the impact of offering a choice between different tests on participation. In the study in Italy (Segnan et al., 2005), participation was lower among subjects who were...

offered a choice between FIT and sigmoidoscopy (27.1%) than among those who were invited to undergo screening with either biennial FIT (28.1–30.1%) or sigmoidoscopy (28.1%), although the difference was not statistically significant. A trial in Australia (Multicentre Australian Colorectal-neoplasia Screening (MACS) Group, 2006) found that the participation rate of people who were offered a choice between FIT, FIT plus sigmoidoscopy, CT colonography, and colonoscopy was not higher than that of those invited to screening with FIT (27% vs 23%; \( P = 0.3 \)). [The Working Group noted that the sample size was rather small, and thus the results were statistically uncertain.]

In a population-based programme in Italy (Senore et al., 2013), the sequential offer of sigmoidoscopy followed by invitation to FIT for those who refused sigmoidoscopy was shown to be an effective approach, resulting in a participation rate of 19% among those who refused sigmoidoscopy. Similar findings have been reported in a pilot screening study in the Netherlands (Hol et al., 2012).

(c) Comparing endoscopy-based and stool-based strategies

The characteristics of studies that compared participation rates in screening with endoscopy-based and stool-based strategies, offered either alone or in combination, are presented in Table 3.6.4.

(i) Sigmoidoscopy and stool-based tests for blood

Three trials compared the participation in relation to invitation to gFOBT plus sigmoidoscopy screening versus gFOBT screening alone in three different countries. In a study in the United Kingdom (Berry et al., 1997), participation in screening with gFOBT was similar to that in gFOBT plus sigmoidoscopy (50% vs 48%), but only 20% of subjects invited to screening with gFOBT plus sigmoidoscopy actually underwent sigmoidoscopy. In a similar study in Denmark (Rasmussen et al., 1999), the participation rate was 40% among subjects invited to screening with gFOBT plus sigmoidoscopy, compared with 52% among those invited to screening with gFOBT alone. Similar results were reported in a study in Sweden (Brevinge et al., 1997) that compared subjects invited to screening with gFOBT and those invited to screening with gFOBT plus sigmoidoscopy (61% vs 39%; \( P < 0.001 \)), but the difference was reduced when comparing subjects invited to screening with gFOBT and those invited to screening with sigmoidoscopy alone (55% vs 49%; \( P < 0.01 \)).

In a trial in Australia, screening with FIT plus sigmoidoscopy was associated with a decrease in participation compared with screening with FIT alone (14% vs 27%; \( P < 0.001 \)) (Multicentre Australian Colorectal-neoplasia Screening (MACS) Group, 2006). In a trial in Italy that randomized the practices of GPs to screening with either gFOBT or sigmoidoscopy, the observed participation rates were 17% with gFOBT and 7% with sigmoidoscopy (\( P < 0.001 \)) (Federici et al., 2006b). In two studies in Italy (Segnan et al., 2005, 2007), the participation among subjects invited to screening with FIT was similar to that among those invited to screening with sigmoidoscopy, with participation rates of 28% and 32%, respectively, in both groups. In a study in the Netherlands (Hol et al., 2010), participation was higher among subjects invited to screening with FIT than among those invited to screening with sigmoidoscopy (61% vs 32%; \( P < 0.001 \)).

(ii) Colonoscopy and stool-based tests for blood

In the COLONPREV study in Spain, participation was lower in the colonoscopy arm than in the FIT arm (34% vs 25%; \( P < 0.001 \)), and if the invited participants were given the opportunity to choose the method, more participants were interested in screening with FIT than in undergoing a colonoscopy (Quintero et al., 2012).
Similar results were reported in a trial in Italy (Segnan et al., 2007), which found lower participation rates with colonoscopy than with FIT screening (27% vs 32%; \( P < 0.001 \)).

In another trial conducted in Italy that randomized the practices of GPs to screening with either gFOBT or colonoscopy, the observed participation rates were 27% with gFOBT and 10% with colonoscopy (\( P < 0.001 \)) (Lisi et al., 2010). Similar findings were reported from a study in Australia (Multicentre Australian Colorectal-neoplasia Screening (MACS) Group, 2006), which found participation rates of 27% with FIT and 18% with colonoscopy (\( P < 0.02 \)). [The Working Group noted that the sample size of the Australian RCT was rather small, and thus the results were statistically uncertain.]

**Meta-analysis**

A recent meta-analysis, which included 9 of the 10 studies considered here, concluded that endoscopy tests were associated with lower participation compared with stool-based tests for blood (RR, 0.67; 95% CI, 0.56–0.80), although the statistical heterogeneity across the studies was high (Hassan et al., 2012).

[The Working Group noted that all studies comparing endoscopy versus stool-based tests for blood reported data on participation for a single invitation round. Hence, this approach tends to overestimate the difference in participation between stool-based tests for blood and endoscopy strategies, because a single endoscopy is efficient to achieve the expected protective effect, whereas repeated testing is required in stool-based tests for blood. For stool-based tests, the proportion of regular attendees tends to decrease over time.]

**Comparing CT colonography and other screening methods (endoscopy-based or stool-based strategies)**

Four studies were identified that compared participation in CT colonography with that in colonoscopy, sigmoidoscopy, or FIT. In the COCOS trial in the Netherlands, Stoop et al. (2012) compared participation in screening with colonoscopy and CT colonography among adults aged 50–74 years. The proportion of invitees that
participated was significantly higher for CT colonography (34%) than for colonoscopy (22%). In the SAVE trial, Sali et al. (2016) investigated the participation rates for FIT, colonoscopy, and CT colonography with reduced or full bowel preparation. A reduced preparation for CT colonography increased the participation rate for CT colonography (28% vs 25%; \( P = 0.047 \)); the participation rate was highest for FIT (50%) and lowest for colonoscopy (14%). In the Proteus trial, Regge et al. (2017) reported that the participation rates of individuals aged 58–60 years who were invited to screening with either CT colonography or sigmoidoscopy were similar (30% vs 27%). Moawad et al. (2010) sought to determine patient preferences between colonoscopy and CT colonography in an open access system. A total of 250 consecutive asymptomatic adults at average risk undergoing CRC screening completed a survey that assessed their reasons for choosing CT colonography rather than colonoscopy. Convenience was the most commonly cited reason for choosing CT colonography over other tests. Of the 250 patients, 91 reported that they would not have undergone screening if an option for CT colonography had not been available, and 95% of adults who had undergone both procedures \((n = 57)\) reported that they preferred CT colonography. Overall, it is generally observed that participation in CT colonography is higher than that in colonoscopy, lower than that in FIT, and similar to that in sigmoidoscopy.

3.6.5 Informed decision-making

Cancer screening should be promoted and offered only if the benefits clearly outweigh the harms. However, because the risk of CRC and death from CRC is relatively low (often in the range of 2–10%), the balance between potential benefits and harms may be different for different individuals. Therefore, it is prudent to involve the target population in the decision-making process about participation in the screening programme. The decision about participation needs to take into account personal values and preferences. Enthusiastic persuasion and “nudging” (the purposeful alteration of choices presented to people, to influence their decisions) for participation in screening programmes are discouraged (Editorial, 2009; Woloshin et al., 2012).

Shared decision-making, a concept that has evolved in recent years, should be used to facilitate an informed choice about whether to participate in cancer screening programmes. For shared decision-making, transparent, comprehensive, and informative facts should be provided about the potential benefits and harms of screening, and the expected burden of the screening test and follow-up procedures should be clearly explained. Informational material for decision-making in cancer screening programmes is often derived with the help of stakeholders and organizations and individuals who are not involved in the screening programme (Editorial, 2009).

Key features of informed decision-making in cancer screening include (i) the use of innovative visual decision aids to facilitate the transfer of information to all target individuals, irrespective of education, SES, and previous knowledge, (ii) the use of absolute risks of disease and absolute effects and harms of the screening tests and of the follow-up treatment, and (iii) frequent updating of decision aids with new knowledge and evidence (Agoritsas et al., 2015).

3.7 Emerging techniques

Several tests for CRC screening are at different stages of development, including new stool-based tests, tests based on visual inspection, and blood-based tests (Table 3.7.1).

3.7.1 Stool-based tests

CRC develops from normal mucosa through a series of cumulative mutations (Vogelstein & Kinzler, 1993). Cellular debris from growing neoplastic lesions is released into the stool effluent, and through that mechanism provides an opportunity to screen for CRC. Currently, one such test is commercially available; it is based in part on detection of DNA with mutations in stool.

(a) Multitarget stool DNA test

(i) Technique

Several stool-based DNA tests have been developed during the past decade. Early efforts focused on panels of genes that are commonly mutated during the progression of cancer (e.g. KRAS, APC, and BAT-26). However, results in screening populations showed poor sensitivity, missing approximately half of the invasive cancers detected at colonoscopy (Imperiale et al., 2004). Increased recognition of the importance of gene methylation as an early marker of cancer prompted the addition of methylated gene markers to the panel. Also, to improve sensitivity, haemoglobin immunoassay was added to the test, leading to a new designation as the multitarget stool DNA (mt-sDNA) test (see Table 3.7.1). Currently, the mt-sDNA test detects KRAS point mutations and aberrantly methylated NDRG4 and BMP3, as well as haemoglobin. B-actin is used to measure DNA quality. Stabilizing buffers have been added to prevent DNA degradation after sample deposit, and improved analytical techniques (e.g. quantitative allele-specific real-time target and signal amplification assay) have been developed (Bailey et al., 2016; Sweetser & Ahlquist, 2016).

No adjustment in diet or medication is needed by the participant to perform the test, but testing should be avoided in cases of diarrhoea or of bleeding due to haemorrhoids or menses. Whole stool is collected in a container that is placed in the toilet bowl, and the participant separately probes the stool for FIT. The participant then adds a preservative to the container and sends out both the container and the probe to the laboratory. The laboratory must receive the sample within 72 hours of collection to be able to process the test.

Processing of the samples occurs at the manufacturer’s laboratory. The results for each marker are incorporated into a logistic regression equation to determine whether the test result is positive or negative (Lidgard et al., 2013); a quantitative value of 183 or more indicates a positive test result (Sweetser & Ahlquist, 2016).

Quality control measures are taken during laboratory processing. Specifically, control samples for the DNA assay and the haemoglobin immunoassay components of the test are run alongside the patient samples to ensure adequate processing.

(ii) Screening performance

Test performance of the newest iteration of the mt-sDNA test was examined in a large screening population (n = 9989) in the USA (Imperiale et al., 2014; Table 3.7.2). In this study, all individuals underwent screening with colonoscopy, FIT, and the mt-sDNA test. In that population, 65 individuals had CRC and 757 had at least one advanced colorectal adenoma. The sensitivity of the mt-sDNA test was 92.3% for cancer and 42.4% for advanced neoplasia, significantly higher than that of FIT (73.8% for cancer and 23% for advanced neoplasia). The mt-sDNA test was also significantly more sensitive than FIT in detecting large (≥ 10 mm) serrated lesions (42.4% vs 5.1%); however, the specificity for the

<sup>d</sup> Advanced adenomas.
non-advanced lesions was 86.6% for the mt-sDNA test compared with 94.9% for FIT. In the mt-sDNA test, the performance of the haemoglobin immunoassay component alone was similar to that of FIT.

[Although this large tandem-design cross-sectional study provided insights into the performance of the mt-sDNA test compared with that of FIT, the Working Group noted that the study did not directly provide information about the comparative effectiveness of the two technologies. The performance of FIT was influenced by the established thresholds for haemoglobin levels, which define a positive test result and determine the sensitivity and the specificity (see Section 3.2.1). To the extent that FIT with a lower haemoglobin threshold is used, the results with FIT can approximate those achieved with the mt-sDNA test in this study, with the potential exception of the detection of serrated lesions and polyps, for which FIT has poor sensitivity (Brenner et al., 2014). Also, the study did not provide a comparison in which the two technologies were applied over time.]

There is evidence that the levels of methylated stool markers increase with age. A single study in 500 individuals who had normal colonoscopy findings and who had a freezer-archived stool sample examined factors associated with the levels of methylated stool markers (Ahlquist et al., 2012). All four genes examined (BMP3, NDRG4, vimentin, and TFPI2) were significantly more methylated with increasing age across the age range studied (44–85 years). No associations were found with the other host factors examined in this analysis (e.g. sex, race, body mass index, alcohol consumption, and smoking status). Therefore, theoretically, the specificity might decrease with age. In the large-scale study in the USA (Imperiale et al., 2014), the specificity of the mt-sDNA test was higher in those younger than 65 years (94%) than in those 65 years and older (87%). [The Working Group noted that these studies were performed in the USA. How this test would function in populations outside the USA is not well studied, and there are some data suggesting that DNA marker panels would need to be adjusted in other populations (Park et al., 2017).]

(iii) Preventive effects

There are no RCTs or observational studies of the mt-sDNA test with outcomes of CRC incidence or CRC mortality. Like for CT colonography, most studies of mt-sDNA effectiveness have been tandem studies of a single screening event in a cohort, comparing the outcome (detection rates of CRC and/or advanced neoplasia) with that of established techniques such as FIT or colonoscopy as the reference standard.

Imperiale et al. (2014) compared the detection rates of the mt-sDNA test with those of FIT and colonoscopy. The study population was asymptomatic adults aged 50–84 years at average risk (who were scheduled for screening colonoscopy); recruitment was weighted towards adults aged 65 years and older, to ensure a higher prevalence of cancer. Among the 12,776 participants who were enrolled in the study, 9,989 had results that could be fully evaluated; on colonoscopy, 65 (0.7%) were found to have colorectal adenocarcinomas (of which 60 were screening-relevant cancers) and 757 (7.6%) had advanced precancerous lesions, i.e. advanced adenomas (adenomatous polyps ≥ 10 mm or with > 25% villous component or with high-grade dysplasia) or sessile serrated lesions 10 mm or larger. By comparison, the mt-sDNA test detected 0.6% with CRC (vs 0.48% with FIT), 0.56% with screening-relevant cancers (vs 0.44% with FIT), and 3.2% with advanced precancerous lesions (vs 2.2% with FIT) (Imperiale et al., 2014). [Although the mt-sDNA test showed higher detection rates than the FIT used in this study, use of a different FIT may have resulted in different findings.]

A second screening study comparing the mt-sDNA test with colonoscopy was undertaken in asymptomatic Alaska Native adults aged
40–85 years who were scheduled for screening or surveillance colonoscopy (Redwood et al., 2016). Alaska Native people face several challenges related to CRC screening: (i) they are at high risk of CRC, with earlier onset; (ii) most live in remote areas, where access to endoscopy is limited and regular screening with any test is challenging; and (iii) there is a high prevalence of endemic gastrointestinal bleeding from Helicobacter pylori gastritis, and hence the specificity of FOBT is poorer (76%) in this population (Redwood et al., 2014). Because of these considerations, there was interest in comparing detection rates of FIT with those of the mt-sDNA test in this population. The primary outcome measure was the detection of CRC, advanced adenomas (adenomatous polyps ≥ 10 mm or with > 25% villous component or with high-grade dysplasia), or sessile serrated lesions 10 mm or larger found on screening or surveillance colonoscopy, described as screening-relevant neoplasia. Advanced adenomas were independently reviewed before unblinding. Among 868 enrolled participants, 661 completed the study, of whom 435 were in the screening group and 226 were in the surveillance group. In the screening group, 50% of the screening-relevant neoplasia were detected by mt-sDNA compared with 31% by FIT ($P = 0.01$), and 45% of the advanced adenomas were detected by mt-sDNA compared with 28% by FIT ($P < 0.05$). Detection rates for sessile serrated lesions ($n = 25$) were not reported separately for the two study groups, but for lesions larger than 10 mm, 67% were detected by mt-sDNA compared with 11% by FIT ($P = 0.07$), and for lesions 10 mm or smaller, 38% were detected by mt-sDNA compared with 6% by FIT ($P = 0.07$). [The Working Group noted that these findings are consistent with those from the study by Imperiale et al. (2014), but that this is a small study in a unique, high-risk population and therefore is not easily generalizable to individuals at average risk of CRC.]

Modelling studies have begun to include the mt-sDNA test in simulations for comparison with other screening tests. Knudsen et al. (2016) examined 17 unique strategies for mt-sDNA screening in their microsimulation model for the USPSTF (for detailed information on the models, see also Section 3.2.6 and Section 3.3.6). The strategies varied the starting and ending ages for screening and used screening intervals of 1 year, 3 years, and 5 years for the test. Annual screening with mt-sDNA at age 50–75 years was efficient (i.e. a strategy that provided the largest incremental increase in LYG per additional screening) or near-efficient (within 98% of the efficient frontier) in all three models; however, mt-sDNA every 3 years, which is recommended by the manufacturer, and every 5 years was not as efficient as the other stool-based tests performed annually. Annual mt-sDNA testing was not a recommended strategy, because its efficiency ratio was lower than the efficiency of the benchmark (i.e. colonoscopy every 10 years at age 50–75 years). However, in terms of deaths averted per 1000 individuals screened, outcomes were similar: 22–24 deaths averted for colonoscopy every 10 years, 22–24 for mt-sDNA testing every year, 19–22 for mt-sDNA testing every 3 years, and 20–23 for FIT every year (Bibbins-Domingo et al., 2016).

Barzi et al. (2017) included mt-sDNA testing at screening intervals of 1 year and 2 years in their comparison of 10-year outcomes for 13 CRC screening strategies. Screening with mt-sDNA every year compared with every 2 years resulted in a negligible difference in the number of diagnosed CRCs (3870 vs 3860), but with both annual and biennial screening, the CRC detection rate exceeded that with one-time colonoscopy (3462). However, the model predicted a smaller reduction in the risk of CRC for annual and biennial screening with mt-sDNA compared with colonoscopy (14% vs 23%), and a smaller reduction in the risk of death from CRC (21% for annual screening with mt-sDNA and 18% for biennial
screening with mt-sDNA vs 34% for colonoscopy) (Barzi et al., 2017).

(iv) Adverse effects

There are no documented adverse effects from the process of undergoing mt-sDNA screening. As with other stool-based screening tests for CRC, adverse effects are associated with follow-up colonoscopy for positive test results, and with false-positive results (see Section 3.2.4). A positive mt-sDNA test result followed by a negative colonoscopy result may be attributable to failure to detect a visible lesion, to very early neoplastic changes that are not yet visible, to the detection by the molecular panel of aerodigestive or supracolonic neoplasms, or to test specificity.

In two screening studies with mt-sDNA (Imperiale et al., 2014; Redwood et al., 2016), the percentage of advanced neoplasia or CRC not detected in follow-up colonoscopies after a positive mt-sDNA result was about 10% (range, 7–13%) and did not fluctuate with age. These patients may undergo more aggressive short-term surveillance because of concerns about a greater range of possible explanations for false-positive findings compared with other stool-based tests.

Cotter et al. (2017) measured outcomes (mortality, incidence, and other symptoms) after a false-positive test result among patients with false-positive and true-negative test results with mt-sDNA. Among 1050 eligible patients (patients with a positive mt-sDNA test result and those with a negative colonoscopy result) with a median follow-up of 4 years, the cumulative incidence of aerodigestive malignancies (8 cases, including 1 CRC, 3 pancreatic cancers, 3 lung cancers, and 1 bile duct cancer) did not exceed the expected incidence, and false-positive status was not associated with excess mortality or “alarm symptoms”. Evidence related to patient anxiety in response to false-positive findings has not been reported.

(v) Cost–effectiveness

In a comparative microsimulation modelling study, Lansdorp-Vogelaar et al. (2010) used the MISCAN and SimCRC models to evaluate the comparative cost–effectiveness of the mt-sDNA test, FIT, sigmoidoscopy, sigmoidoscopy plus FIT, and colonoscopy. The base case evaluated CRC screening intervals of 3 years and 5 years, performance characteristics of the first- and second-generation mt-sDNA tests for detection of adenoma and cancer, and a reimbursement rate of US$ 350. With 100% participation in CRC screening, the models obtained similar reductions in the risk of CRC incidence with 3-yearly and 5-yearly screening with mt-sDNA (30–49%) compared with annual FIT screening (32–40%), but the estimated reduction in the risk of CRC incidence was considerably larger (53–72%) with colonoscopy every 10 years. Compared with other screening tests, mt-sDNA at intervals of 3 years and 5 years was the most costly and least effective screening test, but the costs were still within the conventional criteria for cost–effectiveness (< US$ 15 000 per LYG). The authors concluded that mt-sDNA would be an efficient strategy with the modelled reimbursement rate and screening every 3 years if the participation rate was 50% greater than that of the other screening tests, or if reimbursement costs were less than US$ 60.

Ladabaum & Mannalithara (2016) used a Markov model to evaluate the comparative cost–effectiveness of CRC screening with mt-sDNA every 3 years, FIT every year, and colonoscopy every 10 years in adults at average risk. Despite the improved performance of mt-sDNA over FOBTs, and better sensitivity compared with FIT (see Section 3.7.1(a)(ii)), annual FIT and colonoscopy every 10 years were more effective and less expensive than mt-sDNA every 3 years, assuming 100% participation and a cost–effectiveness threshold of less than US$ 100 000 per QALY gained. Sensitivity analyses produced findings similar to those of the previous study; in
an organized screening programme, mt-sDNA every 3 years would need to achieve greater participation rates of regular screeners (68% vs 50%) and of intermittent screeners (32% vs 27%) compared with FIT, or would need to be reimbursed at 60% less than the base case rate, to be preferred to FIT at the highest threshold (< US$ 100 000 per QALY gained) of cost–effectiveness. With opportunistic screening, based on participation rates of 15% for regular screeners and 30% for intermittent screeners, mt-sDNA would need to achieve nearly twice the participation rate to be under the cost–effectiveness threshold of US$ 100 000 per QALY gained.

(b) Other stool-based tests

Although identification of haemoglobin as a protein marker in stool is a well-recognized screening approach, other stool protein markers have also been evaluated. Generally, evaluation of these other markers has occurred in small observational studies in which detection rates of CRC and advanced neoplasia are estimated. Pyruvate kinase type M2 is a protein that regulates tumour growth and is not specific to CRC. In one meta-analysis that identified 10 individual studies assessing the use of stool pyruvate kinase type M2 in the detection of CRC, the sensitivity of the marker was 79% and the specificity was 81% (Li et al., 2012). Calprotectin is a calcium-binding protein that is found predominantly in neutrophils. In one large prospective evaluation study in a screening population (n = 2321), the sensitivity of this marker for CRC was 63% and the specificity was 76% (Hoff et al., 2004).

Beyond these single protein markers, there is also interest in developing broader panels of proteins present in stool that might be used for screening (Ang et al., 2011; Bosch et al., 2017). However, this work remains preliminary. In addition, there is also interest in examining the faecal microbiome as a screening tool, but this development is largely still at the discovery phase (Yu et al., 2017).

3.7.2 Capsule colonoscopy

Building on capsule technology to evaluate the small bowel, a capsule to evaluate the large bowel was first released and evaluated in 2006 (Eliakim et al., 2006). This technology enables a total colon examination to be performed with no bowel intubation or sedation (Table 3.7.1).

(a) Technique

The technology currently used is a second-generation system with improved performance with respect to imaging of the large bowel. Equipment to perform capsule colonoscopy, which is currently commercially available from a single vendor, requires three components: a capsule, a data recorder, and a workstation to read the acquired images. The ingestible capsule has dimensions of approximately 11 mm x 32 mm. The device has a camera at each end and a battery that enables the capture of images for approximately 10 hours. On the basis of the initial experience, refinements were made to improve the performance of the capsule. The current, second-generation capsule has a viewing angle for each camera of 172°, which enables a near-360° view of the colon. The capsule can capture up to 35 images per second. Another improvement in the technology was the development of an adaptive frame rate; this was made possible in part by real-time communication between the capsule and the data recorder worn by the patient. Finally, data from the recorder are downloaded to a workstation, to assist the clinician with image review (Spada et al., 2015, 2016).

Preparation for capsule colonoscopy is necessary for several important reasons. As is the case for conventional colonoscopy, the quality of the examination can be compromised by residual stool coating the colonic mucosa. In fact, suboptimal preparation is a greater threat to the test performance for capsule colonoscopy than for traditional colonoscopy, because with capsule colonoscopy there is no opportunity to wash
the bowel or remove residual effluent through suction. In addition, there is a requirement to “push” the capsule to and through the colon to complete the examination during the 10-hour battery life of the device (Spada et al., 2015). Generally, colon preparation is accomplished with a full dose (4 L) of polyethylene glycol, of which half is taken the day before the procedure and half on the day of the procedure. Boosting of the movement of the capsule is most commonly accomplished with sodium phosphate (NaP). Preparation also includes dietary adjustment (e.g. a clear liquid diet) the day before the procedure, and occasionally the use of suppositories to assist with capsule excretion. Even with these aggressive preparation and boosting regimens, the quality of the examination can be an issue. In a recent meta-analysis of studies of colon capsule colonoscopy, adequate cleansing levels were achieved in 81% of cases and capsule excretion within the usual battery life (10 hours) was achieved in 90% of cases (Spada et al., 2016).

After the capsule is excreted, the images that were obtained need to be interpreted. Given that the capsule generates thousands of images, reading them can be cumbersome. The reading time can exceed 50 minutes in more than 25% of cases (Farnbacher et al., 2014). There have been efforts to develop computer-assisted reading algorithms, building on similar technology used for the capsule to evaluate the small bowel. The proprietary software can develop previews of significant findings that are tailored by the reader. For example, images of interest can be set to various percentages to enable the reader to have a quick overview of the study. This software was formally assessed in one recent study (Farnbacher et al., 2014). By using such settings, the reader could cut the reading time by 90% while still identifying 98% of patients with at least one significant polypoid finding. The use of such software might facilitate same-day examination of individuals, enabling them to be moved quickly from capsule to colonoscopy because they have at least one lesion that requires polypectomy.

[The Working Group concluded that compared with other structural screening options (e.g. colonoscopy and CT colonography), capsule colonoscopy is more demanding for the patient and the examiner, requiring more intensive procedural preparation, longer patient examination, and extended clinician interpretation times. Prolonged examination and interpretation limit the opportunity for same-day colonoscopy, which avoids two separate colon preparations.]

Some individuals may not be suitable for screening with capsule colonoscopy. For example, individuals with a swallowing disorder are probably not well suited for this test. To reach the colon, the device must traverse the entire proximal gastrointestinal tract, including the small bowel. For individuals with extensive prior surgery and/or known adhesive disease, there is a risk of the capsule becoming stuck in the small bowel. Finally, certain individuals are at higher risk of complications with NaP (e.g. people with hypertension who are taking angiotensin-converting-enzyme inhibitors), and therefore screening by capsule colonoscopy entails more risk for those individuals.

The European Society of Gastrointestinal Endoscopy guideline addressed the use of the colon capsule (Spada et al., 2012). Key recommendations included the use of split-dose polyethylene glycol for the preparation and the use of sodium phosphate boosters where possible. Also, the guideline recommended standardized reporting practices, including for the quality of the preparation, the completeness of the examination, and the description (i.e. size, morphology, location) of identified polyps. The guideline recommended follow-up colonoscopy for those with a polyp 6 mm or larger or three or more polyps of any size, and a follow-up interval of 5 years in a CRC screening setting after a negative examination result.
(b) Screening performance

A large tandem study assessed the performance of capsule colonoscopy in a screening population (Rex et al., 2015). In the final cohort \((n = 695)\), capsule colonoscopy identified individuals with one or more polyps 6 mm or larger with a sensitivity of 81% (95% CI, 77–84%) and a specificity of 93% (95% CI, 91–95%). Four cancers were identified by colonoscopy, and three were detected during the blinded capsule interpretation (per-lesion sensitivity, 75%); the other cancer (a 10 mm sessile lesion) was visible during unblinded review. [In the individual with that cancer, other lesions were identified that would have prompted total colonoscopy.]

A second tandem study in the Czech Republic (Suchanek et al., 2015) assessed the performance of capsule colonoscopy in 236 consecutively enrolled adults older than 50 years. The sensitivity of capsule colonoscopy was 77% for polyps 6 mm or larger, 88% for polyps 10 mm or larger, and 100% for adenomas 10 mm or larger; the specificity was 97% for polyps 6 mm or larger and 99% for polyps 10 mm or larger. Two cancers were diagnosed with both methods. The overall sensitivity and specificity for lesions 10 mm or larger were similar in the two studies (Spada et al., 2016).

Capsule colonoscopy, also referred to as capsule endoscopy, is approved in the USA for examining the proximal colon in patients with incomplete colonoscopies, or for patients who are not candidates for colonoscopy or sedation, but it is not approved for CRC screening in adults at average risk, probably because of the limited data available on performance in a screening population (Rex et al., 2017).

(c) Preventive effects

There are no RCTs or observational studies of capsule colonoscopy with outcomes of CRC incidence or CRC mortality. Like with other emerging technologies, single-test tandem studies comparing the detection rates of cancer and of precursor lesions with capsule colonoscopy and with conventional colonoscopy as the reference standard have been conducted [most of these investigations have been in small, heterogeneous study populations]. In one study evaluating the detection rates with capsule colonoscopy in 689 subjects (Rex et al., 2015), the detection rate for adenomas 6 mm or larger was [14%], and the detection rate for adenomas 10 mm or larger was [5.8%]. The cancer detection rate was [0.4%] (3 of the 4 cancers identified by colonoscopy), and after unblinding the cancer was visible in multiple photos taken by the capsule.

(d) Adverse effects

Few serious adverse events associated with capsule colonoscopy have been documented (Spada et al., 2012, 2016). In a tandem study in a screening population, Rex et al. (2015) reported no serious capsule-related events. Among 884 patients enrolled in the study, 142 non-serious events were reported in 101 patients, of which 128 were related to bowel preparation. Three non-serious events associated with the capsule were related to the procedure; these included gagging, vomiting, and abdominal cramping (Rex et al., 2015). Capsule retention, defined as a capsule that remains in the digestive tract for longer than 2 weeks, occurred in fewer than 2% of patients (Rondonotti, 2017).

(e) Benefit–harm ratio and cost–effectiveness

No data are available on the benefit–harm ratio of capsule colonoscopy. Hassan et al. (2008) used a simulation model to compare capsule colonoscopy with conventional colonoscopy and observed that capsule colonoscopy was less cost-effective than conventional colonoscopy if the participation rates were equal. If the participation rate for capsule colonoscopy was 30% higher than that for conventional colonoscopy, then capsule colonoscopy was more cost-effective than conventional colonoscopy.
3.7.3 Blood-based tests

(a) Single-gene plasma DNA test (mSEPT9 DNA test)

Blood-based DNA tests are another example of a new class of CRC screening tests. Blood testing as a screening test for CRC has been referred to as the “holy grail of cancer detection research” (Ransohoff, 2003), because the barrier to participation is reduced to a single blood draw, which may well be combined with other annual tests (e.g. a cholesterol test) (Table 3.7.1). Although the relative simplicity of this technique is an advantage of this approach, commitment to follow-up testing with colonoscopy (after a positive screening result) remains an important consideration.

(i) Technique

DNA of tumour origin is present in minute quantities in the plasma of patients with cancer (Pawa et al., 2011). To date, it has been more promising to search for tumour-associated methylation changes. Through a well-described process (Payne, 2010), investigators evaluated a host of potentially relevant DNA methylation markers. From that group, the methylated Septin 9 gene (mSEPT9) was selected for further development and evaluation, on the basis of favourable test characteristics in case–control studies for this marker compared with other potential candidate markers (Lofton-Day et al., 2008). Septins as a family of genes have critical functions in multiple cellular processes, including apoptosis (Hall & Russell, 2004).

From the perspective of the patient, the mSEPT9 DNA test requires no preparation, including no changes in diet and no use of medication. The individual undergoes a single phlebotomy, and the sample is sent to the laboratory for processing. The details of the processing vary by the version of the test used (Epi proColon, 2017), but processing requires two steps. In step one, DNA is extracted from the plasma and is subsequently incubated in bisulfite solution, to alter unmethylated cytosine residues in the DNA. In step two, the bisulfite-converted DNA is assayed using real-time duplex polymerase chain reaction, and the presence of mSEPT9 is specifically identified through the use of a fluorescence detection probe. The processing time is estimated to be 8 hours (Lamb & Dhillon, 2017).

The laboratory-based mSEPT9 DNA test has well-described external and internal controls. External controls include known positive and negative samples that are run alongside the patient sample. As an internal control, β-actin DNA is used as a marker of DNA quality.

Variations of the test are approved for use in different countries. In the USA, the United States Food and Drug Administration approved the test for use in people who are unwilling to undergo any other screening test; in Europe and China, a slightly different version of the test for the same marker is approved. Although both are second-generation tests, the version used in the USA requires only one of three replicates to be reported as positive, whereas the version used in Europe requires two of three replicates to be reported as positive (Lamb & Dhillon, 2017).

(ii) Screening performance

The performance of the mSEPT9 DNA test as a screening tool was assessed directly in a large-scale (n = 7941) prospective study (Church et al., 2014). Blood samples were drawn from asymptomatic adults aged 50 years or older at least 1 day before colon preparation was initiated. Colonoscopy was subsequently completed. Results for 53 individuals with cancer and 1457 without neoplasia were available. When the mSEPT9 DNA test was analysed on the basis of two replicate samples, the sensitivity of the test for cancer was 48.2% and the specificity was 91.5%. The sensitivity for the detection of more advanced lesions was higher (e.g. sensitivity of 77.4% for stage IV cancer vs 35% for stage I cancer). In post hoc analyses, the test characteristics were
recalculated using a third replicate sample. The sensitivity increased to 63.9% and, as expected, the specificity decreased to 88.4% (Church et al., 2014). A follow-up analysis of this cohort was also performed using the optimized (i.e. second-generation) test. The sensitivity for detection of CRC increased to 68%, and the specificity decreased to 79% (Potter et al., 2014).

A meta-analysis identified 14 studies that evaluated the performance of the \textit{mSEPT9} DNA test (Zhang et al., 2017). The study design and the application of the test varied across the studies, resulting in significant heterogeneity. For detection of CRC, the pooled sensitivity was 67% (95% CI, 61–73%) and the pooled specificity was 89% (95% CI, 86–92%). In another meta-analysis of 25 studies (Song et al., 2017), 2613 CRC cases and 6030 controls were included, and the sensitivity ranged from 48.2% to 95.6% and the specificity ranged from 79.1% to 99.1%.

As discussed above (see Section 3.7.1(a)(ii)), there is some evidence that methylation of genes increases with age, which has the potential to decrease test specificity in older individuals. Also, analysis by race suggested some increased false-positivity in African American people compared with White people (Potter et al., 2014). In fact, the meta-analysis by Zhang et al. (2017) also demonstrated variation in performance across ethnicity.

\begin{itemize}
\item[(iii)] \textbf{Preventive effects}
\end{itemize}

There are no RCTs or observational studies of plasma DNA tests with outcomes of CRC incidence or CRC mortality. As with other emerging technologies, single-test tandem studies comparing the detection rates of cancer and of precursor lesions are the principal methodological strategy for evaluating the efficacy of the test. Only one evaluation of the \textit{mSEPT9} DNA test has been carried out in an asymptomatic screening population, and it is described above (Church et al., 2014).

Ladabaum \textit{et al.} (2013) estimated the comparative effectiveness of the \textit{mSEPT9} DNA test, FOBT, FIT, sigmoidoscopy, and colonoscopy using a validated decision analytical model. The performance parameters used for the \textit{mSEPT9} DNA test were those observed by Church \textit{et al.} (2014) with two and three replicates with biennial screening. All screening strategies assumed 100% participation. In the base case, screening with the \textit{mSEPT9} DNA test decreased CRC incidence by 35–41% and CRC mortality by 53–61%.

In terms of the comparative effectiveness of the \textit{mSEPT9} DNA test, all of the established screening strategies considered in the analysis were more effective than the \textit{mSEPT9} DNA test.

\begin{itemize}
\item[(iv)] \textbf{Adverse effects}
\end{itemize}

There are no reports of adverse effects of CRC screening with the \textit{mSEPT9} DNA test. Potential adverse effects are those related to the process of phlebotomy (blood draw). With the current low specificity, a significant fraction of asymptomatic adults undergoing screening and receiving positive test results would be referred for colonoscopy, and the risks associated with bowel preparation and colonoscopy would apply.

\begin{itemize}
\item[(v)] \textbf{Benefit–harm ratio and cost–effectiveness}
\end{itemize}

No data were available on the benefit–harm ratio associated with CRC screening with the \textit{mSEPT9} DNA test, and only one study on cost–effectiveness was available to the Working Group. Ladabaum \textit{et al.} (2013) compared the cost–effectiveness of the \textit{mSEPT9} DNA test with that of established screening strategies. In an analysis based on the estimates of specificity and sensitivity from Church \textit{et al.} (2014), CRC screening with the \textit{mSEPT9} DNA test was cost-effective compared with no screening, but not cost-effective compared with established screening tests, because it was less effective and more costly. Because screening participation is variable and is influenced by test preference, comparisons between strategies may yield different results.
For example, FIT was the preferred strategy with 100% participation, but when the participation rate was reduced to less than 70%, it was no longer more effective than the two-reagent mSEPT9 DNA test, and when the participation rate was reduced to less than 85%, it was no longer more effective than the three-reagent mSEPT9 DNA test. [The Working Group noted that where increasing participation in a CRC screening programme depends on the availability of preference-sensitive options, tests that are less effective in head-to-head comparisons than tests that have more favourable characteristics may become more attractive.]

(b) Multiple-gene plasma DNA test

A 29-gene marker panel is currently commercially available and has been marketed in some countries as an option for CRC screening. The gene panel is based on the hypothesis that myelomonocytic cells are recruited to neoplasia and that genes in those cells could be used as biomarkers for detection (Nichita et al., 2014). The test has been assessed within a case–control study that recruited patients in the Republic of Korea and Switzerland. The initial study to develop the panel included 144 individuals, with 46 patients with at least one large polyp, 48 patients with CRC, and 50 controls. The 48 CRCs were equally split (n = 12) across the four stages. Through a process of repeated statistical analysis, a final list of 29 genes was developed to compose the DNA panel. To evaluate the clinical relevance of the 29-gene panel, penalized logistic regression was applied to the data set and the models were validated by non-overlapped bootstrap methods. In the validation model, the sensitivity of the test for the detection of CRC was 75% (Ciarloni et al., 2015).

In a second publication (Ciarloni et al., 2016), the 29-gene test was again examined in a selected population. Although the second study was larger than the initial study (n = 594), only the population in Switzerland was included. Again, a case–control design was used, with 149 controls, 103 patients with at least one large adenoma, and 97 patients with CRC, with a preponderance of late-stage cancers (44 in stages I and II and 53 in stages III and IV). When both sets of tests were considered, the sensitivity for the detection of CRC was 75%, with a higher sensitivity in those with late-stage cancer (90% for stages III and IV vs 56% for stages I and II). The specificity, determined by a negative colonoscopy result, was reported as 92%.

[The Working Group noted that the validation strategies used suggested extreme overfitting of the model and that the test had not been evaluated for test characteristics in a large prospective asymptomatic screening population using colonoscopy as a reference standard. The spectrum of cases was weighted to later-stage disease, and there was evidence that the test characteristics were better in those with more advanced disease.]

3.7.4 Tests based on other markers

(a) Protein markers in serum

There are a host of potential pathways to abnormal protein production during carcinogenesis that could be detected in serum. The protein could be the direct product of an abnormally modified gene. Alternatively, protein products released from inflamed or bleeding tissue associated with cancer might also be detected. Finally, approaches to identify antibodies made in response to neoplastic tissue have also been studied. Tumour-derived markers such as carcinoembryonic antigen and carbohydrate antigens (e.g. CA 19-9) have been extensively studied in serum (Hundt et al., 2007). [The studies on test performance are generally small and have a case–control design.] The results varied according to a variety of factors, including the spectrum of patients with cancer studied (early-vs late-stage disease) and the thresholds used to define a positive test result. Generally, results with such markers have been disappointing, with
sensitivities of about 50% and skewed towards those with more advanced disease. Given the relative lack of sensitivity for individual serum markers, efforts have been made to more broadly study the proteome. Several groups have used mass spectrometric analysis to examine protein patterns in individuals with cancer and those without. Although the studies that have compared the test characteristics of protein patterns with those of tumour markers alone show more promising results (Pawa et al., 2011), those studies are small and cross-sectional in nature.

(b) RNA markers in stool or serum

During the past decade there has been increasing interest in the role of the transcriptome in colorectal carcinogenesis. The initial work focused more directly on protein-coding RNA. Free messenger RNA (mRNA) is not stable in blood. However, mRNA isolated from circulating leukocytes can be analysed. Analyses have been performed of mRNA coding for a host of potentially relevant biological markers (e.g. carcinoembryonic antigen, cytokeratins, and mucins) (Hundt et al., 2007). [In these small studies comparing selected cancer cases with controls, the test characteristics were not appropriate for screening.]

There is growing interest in non-coding RNA as a biomarker for cancer, including CRC (Esteller, 2011; Kita et al., 2017). Perhaps the best-studied species are the microRNAs (miRNAs). These are short (18–22 bp) segments of non-coding RNA. Compared with mRNA, these short segments are more stable and less prone to degradation even at extremes of temperature or pH, and therefore they are better suited as biomarkers (Yiu & Yiu, 2016). miRNAs serve as modulators of the translation of mRNA and can thus influence the growth and development of tumours through a variety of mechanisms. Importantly, they are detectable in both serum and stool. In one representative study examining miRNA in stool, investigators compared miRNA expression in 29 individuals undergoing colonoscopy (10 with CRC). Levels of miR-21 and miR-106a in stool were significantly increased in individuals with CRC compared with those without CRC (Link et al., 2010). [The Working Group noted that although this area of research is developing quickly, the studies are preliminary, focusing on panels of markers in CRC cases and controls. Large-scale studies in screening populations are not available at this time.]

(c) Volatile organic compounds in breath-based tests

There has been some interest in examining volatile organic compounds exhaled through breath as a potential biomarker. Tumour growth has been associated with cell membrane peroxidation and the subsequent emission of volatile organic compounds (Peng et al., 2010). Volatile organic compounds can be identified in several different ways (de Boer et al., 2014). Individual volatile gases can be separated out from a breath sample using gas chromatography–mass spectrometry (GC-MS). Alternatively, a sensor array, which has been called an “electronic nose”, can more broadly evaluate smell prints, driven by the underlying profile of volatile organic compounds.

Studies evaluating the role of volatile organic compounds as a biomarker for CRC are relatively limited (Markar et al., 2015). A proof-of-principle study used trained canine olfaction to distinguish between individuals with cancer and those without. A Labrador retriever, with 33 breath samples, appropriately detected CRC confirmed with colonoscopy, with a sensitivity of 91% and a specificity of 99% (Sonoda et al., 2011). From a clinical standpoint, it would be difficult to implement canine detection into standard laboratory practice, but the study has prompted further work using more traditional approaches to detect volatile organic compounds. For example, separate investigators (Altomare et al., 2013; Amal et al., 2016) have used GC–MS in CRC cases and controls to identify potentially discriminating
volatile organic compounds. Using this type of approach in small numbers of individuals results in sensitivities of approximately 85% and specificities in the range 83–94%. [The Working Group noted that the studies are small and preliminary and require validation. Large-scale prospective evaluations of volatile organic compounds in screening populations have not been performed.]

(d) **Urinary markers**

Urinary markers are under development but are not reviewed here.

**References**

JAMA.2016.5989

3.8 Populations at high risk of colorectal cancer

Populations at high risk for the development of CRC include the following categories of individuals: those with (i) a specific genetic predisposition; (ii) a family history of colorectal neoplasia; (iii) a personal history of colorectal neoplasia (cancer or premalignant lesions); and (iv) pre-existing medical conditions including inflammatory bowel disease, acromegaly, previous uretero-sigmoidostomy, and cystic fibrosis (Table 3.8.1). Because individuals at high risk require more intensive testing, the term “surveillance” is generally used, and the term “screening” is reserved for asymptomatic populations at average risk.

3.8.1 Genetic predisposition

This category includes all individuals with specific genetic characteristics that confer a higher-than-average risk of developing CRC and other cancer types (Table 3.8.2). These genetic abnormalities induce syndromes that can be divided into three broad categories: (i) non-polyposis syndromes, (ii) adenomatous polyposis syndromes, and (iii) non-adenomatous polyposis syndromes. It should be noted that although current strategies for identifying individuals at high risk of CRC consist of syndrome-specific genetic testing, stimulated by the recognition of the phenotype associated with that syndrome and followed by surveillance of affected individuals, there is increasing interest in multigene panel testing for individuals with CRC when a hereditary component is suspected. This is now possible with the advent of massively parallel or next-generation sequencing, and it has been suggested that using a panel of high-penetrance genes associated with CRC in patients referred to cancer genetics services could be an efficient and cost-effective means of identifying genetic predisposition to CRC (Gallego et al., 2015).

(a) Non-polyposis syndromes

(i) Lynch syndrome

Definitions

Lynch syndrome is caused by germline mutations in mismatch repair (MMR) genes (MLH1, MSH2, MSH6, PMS2, and EPCAM), which result in a deficiency in MMR functions and confer an increased risk of developing hypermutated tumours that display high microsatellite instability (MSI-H tumours) (Stoffel & Yurgelun, 2016).

Lynch syndrome is the underlying cause of about 3% of all CRCs and is also associated with ovarian cancer, endometrial cancer, stomach cancer, and other cancer types (Hampel et al., 2008). Lynch syndrome was initially called hereditary non-polyposis CRC (HNPCC), to distinguish it from CRC genetic syndromes with a polyposis phenotype, but this term was later dropped in recognition of the wide range of cancer types to which Lynch syndrome predisposes (Umar et al., 2004). CRCs that arise in patients with Lynch syndrome also suffer loss of one or two of the MMR proteins that are coded for by the MMR genes (Umar et al., 2004). The estimated population prevalence of mutations in MMR genes is about 1 in 3000 (Dunlop et al., 2000). Recent evidence from a large prospective Lynch syndrome database estimated the lifetime risk of any cancer by age 70 years to be about 80%; the cumulative excess risk at age 60 years varies from 46% for MLH1 mutations to 0% for PMS2 mutations (Møller et al., 2017). [These estimates may be attenuated as a result of surveillance.]

CRCs with MMR deficiency account for about 15% of all CRCs, but not all of these are Lynch syndrome cancers; most (12% of all CRCs) are sporadic cancers that arise through the serrated pathway (and are more likely to be located in the proximal colon), in which the MHL1 gene is silenced not by a mutation but by hypermethylation of the promoter region of the gene (Stoffel
Therefore, isolated MSI-H tumours that show MLH1 loss of function are unlikely to be caused by Lynch syndrome. Nevertheless, the presence of a MSI-H tumour heightens the probability of Lynch syndrome, and therefore has important implications for screening and surveillance. In addition, there is evidence that MSI-H tumours do not benefit from adjuvant 5-fluorouracil chemotherapy (Carethers et al., 2004), although, stage for stage, they have a better prognosis compared with non-MSI-H tumours (Gryfe et al., 2000); more recently, evidence has emerged that metastatic MSI-H tumours respond well to immune checkpoint inhibitors (Le et al., 2015).

The Amsterdam family history criteria are a set of diagnostic criteria developed to help identify families with an autosomal dominant pattern of inherited risk of CRC; the criteria are the following: three or more family members with CRC or another Lynch syndrome cancer, in two or more consecutive generations with one case diagnosed at age < 50 years, and one of the affected relatives being a first-degree relative of the other two, with familial adenomatous polyposis excluded (Vasen et al., 1991). However, fewer than 50% of people with identified mutations in MMR genes come from families that fulfil these criteria (Vasen et al., 1991). In addition, about 50% of families that do fulfil the criteria do not have mutations in MMR genes. Such families

are described using the term “familial CRC” (see below).

**Effectiveness of surveillance**

If a carrier of a MMR mutation has been identified, or if a family fulfils the Amsterdam criteria, even in the absence of an identifiable mutation, then endoscopic surveillance is universally recommended. In a case–control study of Lynch syndrome family members, regular colonoscopy at intervals of 3 years was shown to reduce the risk of CRC by 50%, to prevent death from CRC, and to produce a relative reduction in all-cause mortality of 65% (Järvinen et al., 2000). [The Working Group noted that these results were derived from fairly small numbers (133 in the study group and 119 in the control group).] A longitudinal cohort study conducted in the Netherlands reported a 70% reduction in the standardized mortality ratio for CRC after the introduction of colonoscopy every 1–2 years starting at age 20–25 years for Lynch syndrome family members with at least one family member identified with a germline mutation in one of the MMR genes (de Jong et al., 2006).

**Surveillance strategies**

There is debate about the optimal surveillance interval. Three prospective studies (Engel et al., 2010; Vasen et al., 2010; Stuckless et al., 2012) and one retrospective study (Mecklin et al., 2007) have examined the performance of colonoscopy surveillance in Lynch syndrome family members (Table 3.8.3). Most cancers diagnosed between surveillance episodes were diagnosed at an early stage (stage I or II), and most were located in the proximal colon, emphasizing the need for careful proximal colonoscopy. On the basis of these studies, recent European guidelines suggest that the surveillance interval should be 1–2 years (Vasen et al., 2013).

A cost–effectiveness analysis concluded that, on average, regular endoscopic examination confers an increase in life expectancy of 7 years for Lynch syndrome family members, and total colonoscopy is the preferred surveillance modality, given the high risk of adenomas and cancer and the high incidence of lesions in the proximal colon (Vasen et al., 1998). The evidence relating to the age at which surveillance should start indicates that age 25 years is appropriate, because it is from this age that the risk increases substantially, both in those defined by family history (Lynch et al., 1993) and in those with proven mutations (Vasen et al., 1996).

(ii) **Familial colorectal cancer**

**Definition**

The term “familial colorectal cancer”, previously known as familial colorectal cancer type X (FCCTX), is used to describe the 40–50% of families with CRC that fulfil the Amsterdam criteria but are not found to have germline mutations in the MMR genes (Stoffel & Yurgelun, 2016). There is some debate about whether patients with MSI-H tumours with no mutations in MMR genes should be included in this group. Either way, current evidence suggests that this is a genetically heterogeneous group, and although several candidate genes have been identified, no unifying genetic pattern has emerged yet (Muzny et al., 2012).

**Surveillance strategies**

CRC risk is slightly lower in patients with familial CRC than in those with Lynch syndrome (see Section 3.8.1(a)). However, it is generally agreed that even when genetic screening has excluded genetically defined Lynch syndrome, the surveillance strategy in families that fulfil the Amsterdam criteria should be the same as that for patients with Lynch syndrome (Cairns et al., 2010).
(b) Adenomatous polyposis syndromes

(i) Familial adenomatous polyposis

Definition

Familial adenomatous polyposis (FAP) is caused by germline mutations in the adenomatous polyposis coli (APC) gene, a tumour suppressor gene that has a role in Wnt signalling and is mutated in most cases of sporadic CRC that do not display MSI (Muzny et al., 2012). FAP is easily recognized in most patients because of its phenotypic characteristics, consisting of hundreds to thousands of adenomatous polyps throughout the large bowel. The population prevalence is about 1 in 14,000, and FAP accounts for fewer than 1% of all CRCs (Bülow et al., 1995) [this percentage is now about 0.07%, as a result of effective recognition and surgical prophylaxis].

Although FAP displays an autosomal dominant pattern of inheritance, about 25% of cases are not associated with a family history and are caused by new mutations. It is in this de novo subgroup that most of the cancers now arise, because there is no opportunity to identify gene mutation carriers from a family history (Cairns et al., 2010). There is significant phenotypic heterogeneity in FAP mutations, and some mutations are associated with an attenuated form of FAP (attenuated FAP) that leads to fewer polyps and a later age of onset of both polyps and cancer (Sieber et al., 2006). In most cases of FAP, polyposis will develop in the second or third decade of life, and the risk of developing CRC is 90% by age 70 years (Vasen et al., 2008).

FAP is also associated with adenocarcinoma of the duodenum and the ampulla of Vater (lifetime risk, ~7%), diffuse fundic gland polyposis of the stomach, gastric adenomas, and papillary thyroid cancer (Stoffel & Yurgelun, 2016).

Effectiveness of surveillance

During the period from the 1970s to the 1990s, polyposis registries were set up in several countries (including Denmark, Finland, Sweden, and the USA) to improve the management of this condition. In studies based on these registries, the incidence of CRC in symptomatic patients with FAP was much higher than that in asymptomatic individuals with FAP who were under surveillance (47–70% vs 3–10%) (Alm, 1975; Bussey, 1975; Järvinen et al., 1984; Bülow, 1986; Vasen et al., 1990). In addition, the registration of FAP cases followed by regular surveillance consistently reduced CRC-specific mortality (Bertario et al., 1994; Bülow et al., 1995; Belchetz et al., 1996; Heiskanen et al., 2000).

### Surveillance strategies

For classic FAP, it is usual to offer sigmoidoscopy surveillance, because the rectum appears to be affected in all cases. In the case of attenuated FAP, in which the polyp load is smaller and polyps are more likely to be located in the proximal colon, colonoscopy is recommended (Vasen et al., 2008).

In terms of the interval between examinations, because studies on the natural history of FAP indicate that, on average, 10–15 years elapse between the diagnosis of the first adenoma and the development of invasive malignancy, endoscopy (colonoscopy or sigmoidoscopy as recommended) every 2 years is recommended (Bussey, 1975; Vasen et al., 2008).

The age at which endoscopic screening should start is dependent on the risk of developing invasive malignancy. Early studies carried out in the 1970s and 1980s found that the risk of developing CRC before age 20 years is very low, and data from the European FAP registries indicate that no cases have been recorded before age 10 years (Vasen et al., 2008). Therefore, for classic FAP, sigmoidoscopy surveillance is recommended from about age 11 years (Vasen et al., 2008). In attenuated FAP, because the onset of CRC is much later, with no case having been reported before age 24 years (Burt et al., 2004; Nielsen et al., 2007), it is recommended that colonoscopy at intervals of 2 years should start at about age 20 years. The duration of surveillance after the appearance of the first adenomas should be decided jointly by the patient and the surgeon; there may be good reasons for deferring colectomy, but because the risk of CRC increases rapidly after age 25 years (Cairns et al., 2010), it should be carried out before then, unless the polyp load is very small and there is no high-grade dysplasia.

In the unusual situation where no mutation can be identified in an individual with a FAP phenotype, for their first-degree relatives, in whom the risk of having FAP is 50%, annual endoscopic surveillance from the early teenage years until age 30 years, and thereafter every 3–5 years until age 60 years, is recommended by consensus (Cairns et al., 2010).

If colectomy and ileorectal anastomosis have been carried out, lifelong annual endoscopic surveillance is recommended, because the risk of cancer in the remaining large bowel is about 25% (Nugent & Phillips, 1992).

#### (ii) Rare adenomatous polyposis syndromes

**MUTYH-associated polyposis** is an autosomal recessive condition caused by biallelic mutations in MUTYH, a base excision repair gene (Stoffel & Yurgelun, 2016). The phenotype is highly variable, ranging from multiple polyps, both adenomatous and hyperplastic, to CRC in the absence of coexisting polyps. MUTYH-associated polyposis is a rare cause of CRC, but two mutations (Y165C and G382D) have been identified that have a carrier rate of about 1% in populations of European origin (Balaguer et al., 2007).

Polymerase proofreading-associated polyposis (Palles et al., 2013) and constitutional mismatch repair deficiency (Bakry et al., 2014) are caused by germline mutations that increase the risk of CRC; because they are so rare, they are not considered in further detail here.

### Strategies for surveillance

There is no evidence specifically relating to surveillance strategies for these very rare conditions, but a similar approach to that taken with FAP is recommended.

#### (c) Non-adenomatous polyposis syndromes

#### (i) Hamartomatous polyposis syndromes

Peutz–Jeghers syndrome (PJS) results from germline mutations in the STK11 gene, although in about 50% of cases that meet the clinical criteria, genetic testing is negative (Hemminki et al., 1998). Affected individuals develop
multiple hamartomas throughout the gastrointestinal tract and mucocutaneous pigmentation, and have an increased risk of cancer of the colorectum, stomach, and other extraintestinal sites. The lifetime risk of these cancers has been estimated to be between 45% and 90%. The population prevalence is probably about 1 in 50,000, and these cancers account for fewer than 0.01% of all CRCs (Cairns et al., 2010). The cumulative risk by age 70 years is on the order of 40% (Hearle et al., 2006). When a STK11 gene mutation has been identified, complete colonoscopy is recommended at intervals of 2 years from age 25 years (Cairns et al., 2010). Because PJS is rare, the effectiveness of this approach has not been clearly established.

Cowden syndrome, also called PTEN hamartoma tumour syndrome (PHTS), is defined by germline mutations in the PTEN tumour suppressor gene, which is involved in the Akt/PKB signalling pathway, and is associated with an increased risk of a variety of cancer types. The phenotype is highly variable, and in the gastrointestinal tract consists of hamartomas, adenomas, serrated polyps, lipomas, and ganglioneuromas (Heald et al., 2010). When a PTEN gene mutation has been identified, the risk of CRC does appear to be increased, but the increase in risk has not been precisely defined, and definitive guidance for surveillance is not available (Cairns et al., 2010).

Juvenile polyposis syndrome (JPS) is another hamartomatous polyposis syndrome and is associated with mutations in the BMPR1A and SMAD4 genes (Roth et al., 1999; Woodford-Richens et al., 2000). The risk of developing CRC is significant, amounting to 40% (Brosens et al., 2007). The prevalence of JPS is estimated to be 1 in 120,000, and it accounts for fewer than 0.01% of CRCs (Cairns et al., 2010). When a BMPR1A or SMAD4 gene mutation has been identified, colonoscopy is recommended at intervals of 2 years from age 15 years (Cairns et al., 2010). Because JPS is rare, the effectiveness of this approach has not been clearly established.

(ii) Serrated polyposis syndrome

Serrated polyposis syndrome (SPS) is defined as more than 5 serrated colonic polyps proximal to the sigmoid, with at least 2 polyps larger than 10 mm, any serrated polyps in the proximal colon when there is a first-degree relative with SPS, or more than 20 serrated polyps (WHO Classification of Tumours Editorial Board, 2019; Rex et al., 2012). Although germline mutations in the GREM1 and MUTYH genes have been associated with SPS (Jaeger et al., 2012), this is not universal. Individuals with SPS have an increased risk of CRC with MMR deficiency (IJspeert et al., 2017).

When the World Health Organization (WHO) criteria for SPS have been met, or when a GREM1 or MUTYH mutation has been identified, colonoscopy at intervals of 1–2 years is recommended (East et al., 2017) [this is a weak recommendation, based on low-quality evidence]. Recent work indicates that several clinical risk factors could be used to stratify patients with SPS for different surveillance intervals (IJspeert et al., 2017).

3.8.2 Family history of colorectal neoplasia

(a) Definitions

It is well established that individuals with a family history of CRC have a higher risk of developing CRC. A close familial relationship, an early age at diagnosis, and the number of affected relatives are each indicators of elevated risk (Cairns et al., 2010). There is a large body of evidence from observational studies, most of which have been summarized in meta-analyses, which consistently found an approximately 2-fold increased risk of CRC in people with a first-degree relative with CRC compared with people with no such family history (Johns & Houlston, 2001; Baglietto et al., 2006; Butterworth et al., 2006; Johnson et al., 2013; Table 3.8.4).

</table>

CI, confidence interval; FDR, first-degree relative or relatives; SDR, second-degree relative or relatives; yr, year or years.
The risk of CRC can be increased 2–4-fold if two or more first-degree relatives are affected with CRC (Fuchs et al., 1994; Taylor et al., 2010; Schoen et al., 2015; Weigl et al., 2016). The strength of the association decreases with increasing age. In people with a first-degree family history of CRC, the risk of CRC was found to be highest before or at age 40 years and to decrease with age afterwards (Samadder et al., 2015).

If a first-degree relative was diagnosed with CRC before age 50 years, then the risk of CRC was found to be more than 3-fold that of people with no family history of CRC (Butterworth et al., 2006; Taylor et al., 2010), more than 2-fold if the diagnosis was before age 60 years (Johns & Houlston, 2001; Samadder et al., 2014, 2015), and mostly less than 2-fold if the diagnosis was after age 60 years (Taylor et al., 2010; Samadder et al., 2014, 2015).

The risk of CRC in people with a family history of adenomatous polyps has not been as well investigated, and only a few well-designed studies exist (Lowery et al., 2016). Winawer et al. (1996) reported an almost 2-fold increased risk if adenomas were detected in a first-degree relative, and an even higher risk if the adenoma was detected before age 60 years; these findings were later confirmed by other studies (Ahsan et al., 1998; Cottet et al., 2007). A recent study in Hong Kong Special Administrative Region, China, investigated the risk of advanced adenomas in people with a family history of adenomatous polyps and found a much higher risk if the affected first-degree relative had an advanced adenoma compared with any adenoma (Ng et al., 2016). People with one affected second-degree relative were found to have a 20–50% higher risk of CRC, and the risk was somewhat higher with a greater number of affected second-degree relatives or if second-degree relatives were younger than 50 years or younger than 60 years at diagnosis (Taylor et al., 2010; Samadder et al., 2014, 2015; Weigl et al., 2016).

The association of a family history of adenomatous polyps with an increased risk of colorectal neoplasia is presumably due to a combination of heritable factors and shared environmental factors. It is recognized that up to 30% of CRCs are attributable to hereditary factors, but only 5% are attributable to the highly penetrant mutations that account for the syndromes described above (Broderick et al., 2017). It follows that the remainder (25%) are probably caused, at least in part, by the accumulation of low-penetrance genetic variants. Genome-wide association studies (GWAS) have so far identified up to 37 single-nucleotide polymorphisms (SNPs) with a positive association with CRC, although recent meta-analyses did not confirm the association with CRC for 22 of the SNPs (Montazeri et al., 2016). The presence or absence of these SNPs can be used to construct a polygenic risk score, and it has been shown that people with a polygenic risk score in the top 1% have an almost 3-fold increased risk of CRC compared with the population median (Frampton et al., 2016). However, it should be emphasized that the effect of family history cannot be explained entirely by genetic variation, because it has been shown that family history by itself is a risk factor that operates independently from the SNPs that are currently known to be associated with CRC (Weigl et al., 2018).

(b) Surveillance strategies

People with a family history of CRC are generally advised to start CRC screening earlier than the population at average risk. Colonoscopy is the preferred and recommended examination for screening and surveillance in this high-risk group, because a large proportion of cancers are also located in the proximal colon (Slattery & Kerber, 1994; Cairns et al., 2010; Rex et al., 2017). Expert organizations tend to recommend earlier screening with colonoscopy in first-degree relatives of patients with CRC (Table 3.8.5). For example, screening colonoscopy should begin at

age 40 years in the USA and at age 40–45 years in Germany, or at least 10 years before the age at which CRC was diagnosed in the youngest affected first-degree relative (Brenner et al., 2008; GGPO, 2019; Rex et al., 2017). Expert organizations in the United Kingdom recommend screening colonoscopy for people with a family history of CRC starting at age 50–55 years (Cairns et al., 2010). A recent exception to the strong emphasis on colonoscopy is the recommendation of Cancer Council Australia, which recommends screening with FIT biennially in the first 10 years from age 35 years or 40 years, depending on the family history risk category, followed by colonoscopy every 5 years (Cancer Council Australia Colorectal Cancer Guidelines Working Party, 2017). In other countries and regions, development of guidelines is currently under way (PAHO, 2016; Sung et al., 2015).

The most up-to-date guidelines from the United States Multi-Society Task Force on Colorectal Cancer no longer differentiate between a history of CRC and a history of advanced adenomas in first-degree relatives with respect to the timing of the first screening colonoscopy (Rex et al., 2017). Also, the Task Force recommends a shorter surveillance interval of 5 years for those with two first-degree relatives or one first-degree relative younger than 60 years diagnosed with either CRC or advanced adenoma (Rex et al., 2017).

The United Kingdom guidelines recommend colonoscopy intervals every 5 years if CRC was detected in three first-degree relatives (none younger than 50 years) or in two first-degree relatives at a mean age at diagnosis of younger than 60 years (Cairns et al., 2010). European and German guidelines do not support special surveillance intervals for risk groups defined by family history (Dove-Edwin et al., 2005; Malila et al., 2012; GGPO, 2019).

The surveillance interval of 5 years for individuals with affected first-degree relatives was first mentioned in the guidelines for screening and surveillance from the USA in 2003 (Winawer et al., 2003), but evidence for the effectiveness of specific surveillance intervals is lacking. A recent RCT compared the detection rates of advanced adenomas in people with first-degree relatives diagnosed with CRC before age 50 years or with two first-degree relatives diagnosed with CRC at any age, and found no statistically significant difference at colonoscopy after 3 years (3.5%) and after 6 years (6.9%) (Hennink et al., 2015).

Most guidelines incorporate the age of the affected first- or second-degree relatives (< 60 years or ≥ 60 years), to account for the higher risk of CRC if the affected relative was diagnosed at a comparably younger age, which is supported by many studies (e.g. Winawer et al., 1996; Cottet et al., 2007). Still, the population frequency of having first-degree relatives diagnosed with CRC after age 60 years is 3.4%, so it is much more likely than having first-degree relatives diagnosed before age 60 years (0.8%) or before age 50 years (0.3%) (Taylor et al., 2010).

(c) Effectiveness of surveillance

The recommendation for individuals with a family history of CRC and with a negative colonoscopy to undergo another colonoscopy after 5 years instead of after 10 years, as is recommended for people at average risk, is based largely on the assumption that polyps grow more rapidly or transform more rapidly into cancer in this risk group, derived from clinical experience in the absence of empirical evidence. Only recently have a few observational studies actually analysed the effectiveness of colonoscopy in relation to family history of CRC (Brenner et al., 2011; Nishihara et al., 2013; Samadder et al., 2017). All three studies used CRC incidence as the outcome (Table 3.8.6).

In the study by Brenner et al. (2011), a very similar and strong reduction in the risk of CRC was observed if a colonoscopy was performed in the previous 1–10 years, regardless of whether first-degree relatives were affected. Nishihara

et al. (2013) analysed the reduction in CRC risk by time since colonoscopy and found no reduction in risk in people with a first-degree family history of CRC whose most recent colonoscopy was performed more than 5 years earlier, whereas a significant reduction in risk was observed in people with no first-degree family history of CRC. [The Working Group noted that these results should be interpreted with caution with respect to considerations of surveillance intervals, because the studies did not differentiate between positive and negative index colonoscopies and because the absolute risk of CRC in people with a first-degree family history of CRC is generally higher than that in people with no such family history.]

Samadder et al. (2017) investigated the differences in CRC risk by time since a first negative colonoscopy in relation to a first-degree family history of CRC. In that study, which linked the Utah Population Database with cancer registry data and health-care data, the risk of CRC after a negative colonoscopy was generally reduced in individuals with no first-degree family history of CRC (measured up to 10 years after the negative colonoscopy). In individuals with a first-degree family history of CRC, the risk was similarly reduced up to 5 years after a negative colonoscopy; there was also a suggestion of a reduced risk 5–10 years after a negative colonoscopy in this group, but the standardized incidence ratios were not statistically significant for this interval. [The Working Group considered that the authors’ interpretation that the results support a surveillance interval of 5 years in people with a first-degree family history should be interpreted with caution, because of the limited power of the analyses in this risk group.]

3.8.3 Personal history of colorectal neoplasia
(a) Definitions

For a detailed description of the histopathology of colorectal neoplasia, see Section 1.2. Advanced adenomas are characterized by size (≥ 10 mm) and/or high-grade dysplasia and/or villous histology, and are considered high-risk adenomas, although the most common and strongest risk factor among the advanced characteristics is the size of the tumour. Any of these characteristics distinguishes them from non-advanced adenomas.

Sessile serrated lesions and polyps are common, are located mainly in the proximal colon, and are difficult to detect because of their sessile or flat morphology. Sessile serrated lesions smaller than 10 mm with no cytological dysplasia are classified among the low-risk lesions (Lieberman et al., 2012). Sessile serrated lesions 10 mm or larger and sessile serrated lesions with cytological dysplasia are considered to be high-risk lesions, with significant malignant potential (Erichsen et al., 2016). Traditional serrated adenomas are much less common, have a sessile or pedunculated shape, and are located mainly in the distal colon. Because of their malignant potential, they are considered high-risk adenomas (Erichsen et al., 2016).

Patients with a previous history of CRC have an increased risk of developing a subsequent cancer in the remaining colorectum (Bouvier et al., 2008), and in patients with a previous diagnosis of advanced adenoma, the risk of CRC is also increased (Atkin & Saunders, 2002).

(b) Increase in risk of cancer

Studies on the subsequent risk of colorectal neoplasia and CRC mortality in patients with low-risk adenomas and with high-risk adenomas at baseline examination are presented in Table 3.8.7 and Table 3.8.8, respectively.

In an earlier meta-analysis of observational studies, the risk of advanced adenomas

BMI, body mass index; CI, confidence interval; CRC, colorectal cancer; HGD, high-grade dysplasia; HRA, high-risk adenoma; HRT, hormone replacement therapy; NSAIDs, non-steroidal anti-inflammatory drugs; SIR, standardized incidence ratio; SMR, standardized mortality ratio; yr, year or years.
after 5 years in adults with one or two low-risk adenomas was similar to that in the population at average risk (Saini et al., 2006). More recent studies with up to 10 years of follow-up have confirmed no increased risk of CRC over the longer interval (Lieberman et al., 2007; Miller et al., 2010; Brenner et al., 2012; Cottet et al., 2012).

In the National Cancer Institute Pooling Project in the USA, the risk of advanced neoplasia was increased more than 2-fold in people with a history of adenomas of 10–19 mm compared with adenomas smaller than 5 mm, after 3–5 years of follow-up, and was increased 3-fold in people with a history of adenomas 20 mm or larger (Martínez et al., 2009). In the same study, the risk of advanced neoplasia was increased by about 30% if the adenoma showed villous or tubulo-villous histology. However, in that study there was no association of high-grade dysplasia with subsequent occurrence of advanced neoplasia, although such associations were observed in other studies (Winawer et al., 2006; Atkin et al., 2017).

In another study, compared with the reference group with no neoplasia at baseline examination, the risk of advanced neoplasia increased strongly (RR, 6.05–6.87) in patients with adenomas 10 mm or larger, with villous histology and with high-grade dysplasia, after 5.5 years of follow-up (Lieberman et al., 2007). [The Working Group noted the large confidence intervals in these associations.]

(c) Surveillance strategies

The surveillance strategy for individuals with a personal history of colorectal neoplasia depends on the findings at baseline examination (Table 3.8.9). The section below summarizes the currently available surveillance strategies in such populations.

RCTs (European Polyp Surveillance I–III) are currently under way to assess the intervals for follow-up of patients with low-risk adenomas (5 years vs 10 years) and compared with those with high-risk adenomas (3 years vs 5 years) (Jover et al., 2016).

(i) One or two tubular adenomas smaller than 10 mm at baseline examination

As a result of improvements in colonoscopy, the detection rates of polyps, particularly those of small polyps, have increased (Brenner et al., 2015). Findings of one or two tubular adenomas with no villous components or high-grade dysplasia are considered to be low-risk adenomas.

Recent expert guidelines from countries with long-standing screening practices, such as the USA and countries in Europe, generally recommend having surveillance colonoscopy 5–10 years after the removal of low-risk adenomas (Lieberman et al., 2012; Hassan et al., 2013), or following recommendations for the next screening as if there had been no relevant findings at colonoscopy (Atkin et al., 2012). The United Kingdom guidelines recommend surveillance after 5 years, or no surveillance (Cairns et al., 2010) (see Table 3.8.9).

A recent meta-analysis and two individual studies that have not yet been considered in the existing guidelines observed a lower risk of CRC incidence and mortality after the removal of low-risk adenomas compared with that in the general population at average risk. These results, in addition to the results of earlier studies, challenge current recommendations and suggest that an extended interval of surveillance or no surveillance may apply after the removal of low-risk adenomas (Atkin et al., 2017; Dubé et al., 2017; Løberg et al., 2017). [The Working Group noted that in the studies of Atkin et al. (2017) and Løberg et al. (2017) the definitions of low-risk adenomas were more inclusive than only one or two adenomas smaller than 10 mm.]

yr, year or years.
(ii) Three or more adenomas at baseline examination

Patients with three or more adenomas at baseline examination have an increased risk of colorectal neoplasia soon after the baseline examination. It is assumed that with the prevalence of multiple adenomas, single adenomas may be missed; this may explain, at least in part, the higher adenoma detection rates at follow-up examinations (Lieberman et al., 2012). In an analysis of the National Cancer Institute Pooling Project, the risk of advanced adenomas during a follow-up of 3–5 years increased in a linear manner with each additional adenoma detected at baseline (Martínez et al., 2009).

According to guidelines from the USA and the European Society of Gastroenterology, patients with 3–10 adenomas smaller than 10 mm are considered to have a high risk of colorectal neoplasia and are advised to have surveillance colonoscopy 3 years after the baseline examination. According to guidelines from Australia, the European Union, and the United Kingdom, patients with three or four small adenomas are considered to be an intermediate-risk group, and surveillance after 3 years is recommended, whereas patients with five or more small adenomas are classified as a high-risk group, and a surveillance interval of 1 year is recommended (Cairns et al., 2010; Atkin et al., 2012; Barclay et al., 2013). For the small group of patients with more than 10 adenomas at baseline examination, the recommendation is to have genetic counselling or surveillance colonoscopy within less than 3 years (Lieberman et al., 2012; Hassan et al., 2013).

(iii) One or more advanced adenomas at baseline examination

Patients with one or more advanced adenomas belong to the high-risk group. Guidelines from Europe and the USA recommend that such patients undergo surveillance colonoscopy after 3 years (Atkin et al., 2012; Lieberman et al., 2012; Hassan et al., 2013); the European Union guidelines also suggest surveillance after 1 year if an adenoma is 20 mm or larger (Atkin et al., 2012). The United Kingdom guidelines recommend a surveillance interval of 3 years if one or two adenomas are 10 mm or larger (intermediate risk) and a surveillance interval of 1 year if at least three adenomas are 10 mm or larger (high risk) (Cairns et al., 2010). The guidelines from Australia recommend a surveillance interval of 3 years after the detection of one to four adenomas 10 mm or larger, and a surveillance interval of 1 year after the detection of five to nine adenomas 10 mm or larger (Barclay et al., 2013).

(iv) Serrated lesions and polyps at baseline examination

The quality of evidence with respect to surveillance after the removal of serrated lesions and polyps is still low and limited (Hiraoka et al., 2010; Schreiner et al., 2010; Lieberman et al., 2012; Holme et al., 2015; Szylberg et al., 2015; East et al., 2017; Dekker & IJspeert, 2018). Expert guidelines from Europe and the USA recommend surveillance colonoscopy after 3 years for patients with high-risk serrated polyps and lesions, and after 5 years for those with low-risk serrated polyps and lesions (Lieberman et al., 2012; Hassan et al., 2013). The United Kingdom guidelines also recommend a surveillance interval of 3 years for patients with high-risk serrated adenomas, but no special surveillance is recommended for those with low-risk serrated polyps and lesions (Cairns et al., 2010).

3.8.4 Medical conditions

Several medical conditions have been associated with the risk of developing CRC: inflammatory bowel disease, acromegaly, ureterosigmoidostomy, and cystic fibrosis.

Patients with inflammatory bowel disease, both ulcerative colitis and Crohn disease, have
an increased risk of CRC. Patients with a long history of extensive colitis (> 10 years with > 50% involvement of the colon) have 7 times the risk of patients with inflammatory bowel disease of lesser severity (Beaugerie et al., 2013). In addition, patients with ulcerative colitis with primary sclerosing cholangitis have a 4-fold increased risk of CRC compared with those without ulcerative colitis, and have an increased risk from the time of diagnosis (Soetikno et al., 2002).

Acromegaly is caused by increased levels of circulating growth hormone and its tissue mediator, insulin-like growth factor 1 (IGF-1). Although acromegaly is rare, this condition has been recognized as a risk factor for CRC and adenomas; prospective studies have found an odds ratio of 1.9 for adenoma and of 6.0 for CRC (Jenkins, 2006).

Adenomas and adenocarcinomas can form at the anastomosis site after ureterosigmoidostomy, although it is unclear whether they arise from the colonic or ureteric epithelium. It has been estimated that this occurs in 2.6% of patients, with a median latency of 26 years (Kälble et al., 2011).

Cystic fibrosis is also known to be associated with an increased risk of CRC, and the risk of CRC is higher in individuals who have had an organ transplant (Gini et al., 2018).

References

4.1 Colorectal cancer

Colorectal cancer (CRC) is the third most common cancer in men and the second most common cancer in women worldwide (with an estimated 1.8 million new cases in 2018) and represented more than 10% of the global cancer burden in 2018. There were an estimated 862,000 deaths from CRC in 2018. CRC incidence rates show a strong positive gradient with the level of economic development; the highest rates of CRC are observed in Australia and New Zealand, Europe, and North America, where incidence rates can be 10 times those observed in Africa and parts of Asia. For patients diagnosed in 2010–2014, 5-year net survival was between 60% and 70% in most countries in North America and western Europe, and less than 50% in several countries in Africa, Asia, eastern Europe, and South America, in some of which it was less than 40%. There is variation between countries in the direction and the extent to which incidence and mortality rates are changing over time.

CRC develops mainly from classical adenomas and serrated polyps, which have different molecular backgrounds and give rise to distinct molecular types of CRC. CRC can be classified on the basis of histology, molecular background, and location within the large bowel, and these subtypes vary in clinical characteristics, response to treatment, and outcome. Advanced adenomas have the highest risk of developing into CRC. Precursor lesions can be detected and removed during screening and follow-up colonoscopy.

Stage describes the state of progression of cancer. A large variation in CRC stage is observed worldwide, depending on diagnostic resources, availability of screening, cancer awareness, and health-care organization. Stage at diagnosis is intrinsically linked with outcome: 5-year survival can be as high as 98% for stage I CRC, compared with less than 20% for stage IV CRC in the same setting.

Most CRCs occur sporadically, and a large fraction of the burden is attributable to lifestyle – and potentially modifiable – risk factors of small magnitude. Risk factors for CRC include increased consumption of processed meat, consumption of alcoholic beverages, tobacco smoking, and excess body fatness and abdominal fatness, whereas CRC risk decreases with consumption of dietary fibre, consumption of dairy products, and being physically active. Other risk factors for CRC include non-modifiable host factors such as increasing age, being male, tall stature, and ethnicity. Use of aspirin and other non-steroidal anti-inflammatory drugs effectively reduces the risk of CRC, with duration–risk relationships. However, these medications increase the risk of several diseases and are not recommended for chemoprevention (see Section 4.9.4).
4.2 Colorectal cancer screening worldwide

4.2.1 Europe

In the European Union, the implementation of international cooperative projects contributed to the development of a common framework for the implementation of population-based organized CRC screening programmes. By 2016, population-based organized programmes had been established or piloted in 22 of the 28 European Union Member States. Three European Union countries (Germany, Greece, and Latvia) have opportunistic screening, and Germany is planning to start a population-based programme in 2019. Non-EU countries have less well-developed programmes. Population-based programmes have been started or piloted in 7 of the 19 non-EU countries in Europe (Georgia, Monaco, Montenegro, Norway, San Marino, Serbia, and Switzerland), and opportunistic screening is available in one country (Bosnia and Herzegovina). Most organized programmes have adopted the faecal immunochemical test (FIT) or are in the process of switching from the guaiac faecal occult blood test (gFOBT) to FIT. Colonoscopy is recommended together with FIT in Austria, Germany, and Greece (opportunistic settings). Among countries with population-based programmes, the Czech Republic, Luxembourg, and Switzerland also offer the option to choose between colonoscopy and FIT. Poland is piloting a population-based programme with colonoscopy. Sigmoidoscopy screening has been implemented in two population-based programmes – in England and in Italy (Piedmont) – and in the pilot programme in Norway, in combination with FIT. The European Union guidelines provide evidence-based recommendations on the quality assurance requirements when implementing CRC screening programmes, covering the different phases of the process. Quality assurance initiatives that focus more specifically on the laboratory standards for FIT and on endoscopy services have also been implemented, facilitating national and international comparisons and benchmarking.

4.2.2 Canada and the USA

Screening for CRC was pioneered in the USA; CRC screening in that country is mainly opportunistic, and different modalities (FIT, sigmoidoscopy, colonoscopy, computed tomography colonography, and the multitarget stool DNA test) are recommended by different bodies in different settings. Colonoscopy is the predominant choice. In Canada, a population-based CRC screening programme with gFOBT or FIT has been launched to cover all 10 provinces but not the territories.

4.2.3 Latin America

Of the 21 countries in Central America, South America, and the Spanish-speaking countries of the Caribbean, only Argentina, Brazil, and Chile have population-based pilot CRC screening programmes, in urban areas, with FIT. Six countries (Colombia, Cuba, Ecuador, Mexico, Puerto Rico, and Uruguay) offer opportunistic screening with clinical guidelines, with gFOBT or FIT.

4.2.4 Africa

In African countries, apart from a pilot demonstration research project initiated by IARC/World Health Organization designed to promote voluntary participation in FIT screening in Morocco, no other CRC screening initiative was identified by recent surveys that collected information about current screening activities.

4.2.5 Central, West, and South Asia

In Central, West, and South Asia, population-based organized screening with FIT was implemented in Bahrain (pilot study), Israel,
Kuwait (pilot study), Qatar, and the United Arab Emirates. Opportunistic screening is offered in the Islamic Republic of Iran, Lebanon, Saudi Arabia, and Turkey.

4.2.6 East and South-East Asia

In East Asia, Hong Kong Special Administrative Region (China) (pilot study), the Republic of Korea, and Taiwan (China) have organized screening programmes with FIT. In China, a CRC screening programme was started in 2006, but it has been implemented only in a small proportion of the target population and covers a limited part of the country. In Japan, CRC screening is primarily opportunistic, with some community-based organized programmes.

In South-East Asia, only Singapore has a national screening programme, and Thailand plans to start a national programme in 2018, following the results of a pilot study launched in 2011. Both countries offer FIT screening. Opportunistic screening is offered in Brunei Darussalam, Malaysia, and the Philippines.

4.2.7 Oceania

In Oceania, population-based organized CRC screening programmes are being rolled out in Australia and New Zealand. Both countries have national guidelines, with FIT-based programmes. No organized population-based CRC screening programmes have been implemented in the other countries in the region.

4.3 Stool-based tests for blood

4.3.1 Techniques

Stool-based tests for blood for CRC screening, or faecal occult blood tests (FOBT), can be broadly separated into two methods. The guaiac faecal occult blood test (gFOBT) is an indirect method that detects blood by means of a chemical reaction based on the peroxidase activity of haemoglobin that reacts with paper impregnated with guaiac. The faecal immunochemical test (FIT) is a method based on a specific antigen–antibody reaction where the antibody binds exclusively to human haemoglobin.

gFOBT does not exclusively detect human haemoglobin, and therefore other sources of peroxidase activity, such as raw or half-cooked meat or some uncooked vegetables, could lead to a positive result. In contrast, antioxidants in drugs or foods (e.g. vitamin C) block the peroxidase reaction, potentially leading to a negative test result. gFOBT can be analysed with or without rehydration. In general, gFOBT does not detect faecal haemoglobin concentrations of less than approximately 600 μg Hb/g faeces, although the analytical sensitivity is higher when gFOBT is rehydrated or with the newer high-sensitivity gFOBT. The clinical sensitivity of a single gFOBT (of any type) is in the range of 16–31% for the detection of advanced neoplasia and 25–38% for CRC, and the average specificity for CRC is 98%.

FIT detects colonic human blood with high analytical sensitivity. It is available in a qualitative form (based on immunochromatography) or in a quantitative form (based on immunoturbidimetry). In general, compared with gFOBT, FIT detects lower levels of faecal haemoglobin at concentrations ranging from 1 μg to 300 μg haemoglobin/g faeces, depending on the manufacturer. The sensitivity of a single FIT is in the range of 27–67% for the detection of advanced neoplasia and 61–91% for CRC, and the specificity ranges from 91% to 98%, depending on the cut-off values and FIT strategies used.

4.3.2 Randomized controlled trials of screening with gFOBT

Four individually randomized trials of annual or biennial gFOBT screening with individual randomization in populations at average risk aged 45–80 years and conducted in different countries have shown significant reductions in
CRC mortality (relative risk [RR] for invitation ranging from 0.68 to 0.91: corrected RR for participation ranging from 0.65 to 0.82), after 9–30 years of follow-up. One of the meta-analyses, published in 2006, which included only the biennial gFOBT screening arms of three of the randomized controlled trials (RCTs), showed a significant reduction of 13% in CRC mortality associated with invitation to screening, whereas the other three meta-analyses of four RCTs, which included the single RCT conducted in the USA with an annual screening arm, reported a reduction of 16–18% in CRC mortality.

The one RCT that used gFOBT with rehydration in most samples and had extended follow-up, conducted in the USA, observed a reduction in CRC incidence of 20% (95% confidence interval [CI], 0.70–0.90) for annual screening and 17% (95% CI, 0.73–0.94) for biennial screening, after 18 years of follow-up in individuals aged 50–80 years.

There is no published evidence from individually randomized trials on the efficacy of FIT screening in reducing CRC mortality or incidence in screening populations at average risk.

4.3.3 Observational studies on preventive effects of stool-based tests for blood

(a) gFOBT screening and reduction in colorectal cancer mortality and incidence

A total of five cohort studies and five case–control studies of gFOBT conducted in screening settings in different geographical regions reported on CRC mortality and/or incidence. The two larger cohort studies of biennial gFOBT without rehydration, with 10–21 years of follow-up, showed reductions in CRC mortality of 10–13%, which remained significant in all scenarios after adjusting for screening participation. Four case–control studies conducted in the USA and in Europe reported a reduction in CRC mortality of 40% on average when comparing screened versus non-screened individuals, although this could be overestimated because of inherent limitations of the study design. A recent meta-analysis based on 17 studies in a screening setting showed an overall significant reduction of 18% in CRC mortality in relation to gFOBT screening (any interval), with similar results in separate analyses of observational studies and of RCTs.

Overall, the available evidence did not point towards a consistent reduction in CRC incidence with gFOBT screening. Only one of three cohort studies, reporting on CRC incidence in Denmark, found a significant reduction after approximately 3.5 years of gFOBT screening without rehydration, and the magnitude of the reduction in CRC incidence was only 6% when comparing screened versus non-screened individuals of the same age.

(b) FIT screening and reduction in colorectal cancer mortality and incidence

The body of evidence for FIT screening and CRC mortality and incidence is small, but the findings are consistent throughout.

Two large cohort studies conducted in Italy, with 8 years and 15 years of follow-up and four or more rounds of biennial FIT screening in individuals aged 50–70 years, and one study in Taiwan, China, with biennial FIT screening and shorter follow-up, all reported significant reductions of up to 40% in CRC mortality. In addition, one case–control study in Japan with annual FIT screening observed substantial CRC mortality reduction up to 2 years after the last screen. One ecological study in Italy, comparing two similar geographical areas with early screening (three or four rounds) versus late screening (one round) with biennial FIT and adjusting for age and sex, provided evidence of CRC mortality reduction in the group screened for a longer period.

Significant reductions in CRC incidence of 10% and 22% were reported in the two Italian cohort studies after 8 years and 15 years of follow-up, respectively. In addition, one ecological study conducted in Italy provided some indication of reduced CRC incidence after
20–24 years of follow-up only in the area that had started with screening earlier, screened biennially for eight rounds with gFOBT, and for five rounds with FIT thereafter.

4.3.4 Adverse effects of screening with stool-based tests for blood

The most commonly reported harms in relation to screening with stool-based tests for blood are psychological consequences as a result of screening per se. One trial showed no significant difference between psychiatric morbidity or suicide rates before and after gFOBT screening. Several studies showed moderate to high anxiety after a positive screening result, but this returns to pre-screening levels immediately after a subsequent negative screening result (either a second gFOBT or a colonoscopy). No associations were observed between an inappropriate reaction (e.g. ignoring subsequent cancer symptoms) after a negative gFOBT screening result and delayed diagnosis. CRC detected after a negative screening result (an interval cancer) had earlier stage at diagnosis than CRC detected in non-screened individuals, but later stage at diagnosis than screen-detected CRC. There are no reports of physical harms directly associated with FOBT screening. There are rare serious harms from colonoscopy or sigmoidoscopy used to evaluate individuals with a positive screening result from a stool-based test for blood. These include bleeding, perforation of the colon, and other serious complications leading to hospitalization. They occur in less than 1 in 10 000 FOBT screens in populations at average risk. Based on the four RCTs, there is no net overdiagnosis associated with gFOBT screening, given that the cumulative incidence of CRC in the screening arm was very similar to or lower than that in the control arm.

4.3.5 Benefit–harm ratio and cost–effectiveness of screening with stool-based tests for blood

CRC screening with gFOBT or FIT provides gains in quality-adjusted life years compared with no screening. Screening annually with higher-sensitivity gFOBT or FIT leads to higher quality-adjusted life years gained than screening biennially but requires more screening resources. Furthermore, costs per quality-adjusted life year gained were less than US$ 30 000 with FOBT screening, even showing cost savings compared with no screening. The cost–effectiveness of CRC screening with stool-based tests for blood has been evaluated across the world, with reports from Asia, Europe, and North America showing benefit with acceptable levels of cost. The cost estimates showed wide variability, owing to the variation in costs between countries; therefore, the cost per life year gained from different studies can only be compared qualitatively.

4.4 Endoscopic methods

4.4.1 Techniques

Sigmoidoscopy and colonoscopy are the two endoscopic techniques used for CRC screening. Their primary screening goal is the detection of early cancer and precancerous polyps.

The requirements for endoscopic procedures include a trained endoscopist (physician or non-physician), endoscopic equipment, support staff for biopsies and similar procedures, and provisions for patient comfort (physical setting and sedation, as appropriate).

Substantial data exist on performance and training for both physician and non-physician endoscopists. Several competency standards and quality measures are recommended for lower gastrointestinal endoscopy. Different skill levels are required for different procedures, and skill levels vary substantially by setting; proposed
skill criteria for each examination exist for international standardization. A recent European guideline noted 44 different performance measures, many of which evaluate processes (e.g. documentation of certain findings) rather than evidence-based factors that influence outcomes. Additional recommendations exist for particular techniques, such as endoscopic polypectomy and endoscopic mucosal resection. The primary screening performance quality metrics for endoscopic screening are completion of the examination to the minimum desired extent (typically the junction of the sigmoid and the descending colon for sigmoidoscopy and the caecum for colonoscopy), adequacy of bowel preparation, and thoroughness of the endoscopic inspection (adenoma detection rate).

4.4.2 Randomized controlled trials of screening with sigmoidoscopy

Four large RCTs of sigmoidoscopy screening have been performed, in Italy, Norway, the United Kingdom, and the USA. All four trials were initiated in the 1990s. The RCTs ranged in size from approximately 34 000 subjects to 170 000 subjects. The three trials in Europe had once-only screening, and the trial in the USA had two rounds of screening; the median follow-up was about 11 years for all the trials. The RCTs consistently showed reductions in risk of CRC incidence and mortality, with relative risks in the range of 0.77–0.82 for CRC incidence and 0.69–0.78 for CRC mortality. All of the results for incidence were statistically significant, and all but one of the results for mortality were significant. An extended follow-up of one trial, with a median follow-up of 17 years, showed a persistent CRC incidence and mortality benefit, with relative risks of 0.74 for incidence and 0.70 for mortality.

In the meta-analyses of the four RCTs reported, the meta-relative risks were in the range of 0.78–0.79 for incidence and 0.72–0.74 for mortality. When stratified by anatomical location, the risk reduction was more substantial for distal CRC than for proximal CRC and was significant only for distal CRC (RR, 0.71 for incidence and 0.63 for mortality). In a pooled analysis of three RCTs that stratified by sex, the risk reduction was significant for both men and women, for both incidence and mortality.

A meta-analysis of the four RCTs found a small reduction in all-cause mortality (RR, 0.97; 95% CI, 0.96–0.99).

4.4.3 Observational studies on preventive effects of endoscopy

There are few large high-quality observational studies that have evaluated the preventive effects of endoscopy in population-based screening programmes. Only those studies that were conducted in a screening setting and that did not exclude prevalent cancers at baseline were included.

(a) Sigmoidoscopy screening and reduction in colorectal cancer incidence and mortality

The most recent meta-analysis of the effectiveness of sigmoidoscopy screening included two cohort studies and seven case–control studies published in 1992–2013. The estimated risk reduction for CRC incidence with sigmoidoscopy screening was 49% (RR, 0.51; 95% CI, 0.39–0.65) (based on five studies). The risk reduction was larger for distal CRC than for proximal CRC (five studies).

The estimated risk reduction for CRC mortality with sigmoidoscopy screening was 47% (RR, 0.53; 95% CI, 0.30–0.97) (based on three studies), with a mortality reduction of 66% for distal CRC but no significant mortality reduction for proximal CRC (four studies). These risk reductions for overall CRC and for distal CRC are comparable to those from the adjusted per-protocol analyses from the RCTs. One more recent large case–control study found mortality reductions for overall CRC (36%) and both
distal CRC (48%) and proximal CRC (25%) after 10 years of follow-up.

(b) Colonoscopy screening and reduction in colorectal cancer incidence and mortality

The most recent meta-analysis of observational studies of the effectiveness of colonoscopy screening included three cohort studies and three case–control studies published in 2005–2014. The estimated risk reduction for CRC incidence with colonoscopy screening was 69% (RR, 0.31; 95% CI, 0.12–0.77) (based on five studies). An additional large case–control study, published after this meta-analysis, found significant incidence reductions for overall CRC (43%) and both distal CRC (55%) and proximal CRC (35%).

The estimated risk reduction for CRC mortality with colonoscopy screening was 68% (RR, 0.32; 95% CI, 0.23–0.43) in the meta-analysis (based on three studies); the results of subsequent studies (one cohort study and one case–control study) concurred with these findings. A recent large case–control study found significant mortality reductions for both distal CRC (75%) and proximal CRC (65%) after 10 years of follow-up.

4.4.4 Adverse effects of screening with endoscopic techniques

The proportion of individuals who undergo a screening sigmoidoscopy that results in a follow-up colonoscopy and who will ultimately not be diagnosed with any cancerous or precancerous lesions (false-positive results) is not well reported in studies. The percentages of patients referred for colonoscopy after sigmoidoscopy in the RCTs ranged from 5% to 23%, depending on referral criteria. False-positive results are not an issue for primary colonoscopy screening, in which, if it is appropriate, polyps can be removed during the screening procedure and no further assessment is required.

The proportion of overdiagnosis of CRC from endoscopy screening is uncertain, because it is not possible to disentangle overdiagnosis from the preventive effect of endoscopy screening. Because endoscopy screening has been demonstrated to significantly reduce CRC incidence, the rate of overdiagnosis is smaller than the preventive effect of endoscopy screening. Overtreatment of precancerous lesions is considerable, but the harm is modest.

Complications in CRC screening with sigmoidoscopy or colonoscopy that are defined as serious include death within 30 days and hospitalization within 30 days because of serious bleeding or perforation. For colonoscopy, perforation rates in two of the trials currently under way were 0.08–0.2 per 1000 procedures. In the two trials and three meta-analyses of population-based studies, bleeding rates were 0.8–2.4 per 1000 procedures.

Compared with colonoscopy, sigmoidoscopy has fewer adverse effects, requires less bowel preparation, and poses a lower risk of bowel perforation. In a population at average risk, perforations from sigmoidoscopy were relatively uncommon (0.1 per 1000 procedures), as were episodes of major bleeding (0.2 per 1000 procedures). The patient factors associated with endoscopy-related major bleeding or perforation were increased age and having a polypectomy.

On the basis of a few large-scale studies, the mortality rate within 30 days associated with endoscopic procedures was estimated to be 1 in 15 000.

The risks of less serious complications are less well documented. The few studies on the psychological consequences in individuals who were not found to have an advanced neoplasia at sigmoidoscopy have suggested that these effects, if any, are transient.
4.4.5 Benefit–harm ratio of screening with endoscopic techniques

To assess the benefit–harm ratio, the systematic review and decision analysis of the United States Preventive Services Task Force estimated that repeated colonoscopy at ages 50 years, 60 years, and 70 years could result in 250–275 life years gained per 1000 individuals aged 40 years requiring an average of just more than four colonoscopies in a lifetime (including surveillance colonoscopies), corresponding to 14.5–16.5 colonoscopies per life year gained.

Modelling studies estimated the quality-adjusted life years gained with screening to be positive, consistently demonstrating that the benefits of endoscopy screening outweigh its harms, with an estimated net benefit of endoscopy screening in the range of 50–125 quality-adjusted life years per 1000 individuals screened starting at age 50 years. Estimates for disability-adjusted life years averted were also consistently positive; these were lower than the estimated quality-adjusted life years gained, but the populations were not comparable between the analyses.

Most modelling studies showed that CRC screening with either colonoscopy or sigmoidoscopy is cost-effective across different willingness-to-pay thresholds. The studies assumed that screening started no earlier than age 40 years and stopped no later than age 80 years. The results from studies that addressed the optimal age at which to start or stop screening, or the optimal screening interval, were inconsistent.

Modelling estimates are based largely on data from settings with high CRC incidence and high income. Therefore, the results of these studies may not easily be transferable to other settings.

4.5 Comparison of the preventive effects of endoscopic methods and stool-based tests for blood

4.5.1 Reduction in colorectal cancer incidence or mortality

The most recent update of an indirect meta-analysis of RCTs comparing CRC screening strategies suggested that sigmoidoscopy is more effective than gFOBT in reducing CRC incidence (RR, 0.84; 95% predictive interval, 0.72–0.97) but not CRC mortality (RR, 0.89; 95% predictive interval, 0.68–1.17). Of note, the meta-analysis did not take into account the most recent updates of the sigmoidoscopy RCTs.

Another indirect meta-analysis, including RCTs and observational studies in a screening setting, suggested that colonoscopy may be more effective than both sigmoidoscopy (RR, 0.56; 95% CI, 0.32–0.94) and gFOBT (RR, 0.49; 95% CI, 0.30–0.76) in reducing CRC mortality.

4.5.2 Detection rates of adenoma and colorectal cancer

Two meta-analyses of RCTs compared the detection rates of advanced neoplasia, advanced adenoma, or CRC across screening modalities. One of the meta-analyses reported that endoscopic techniques (colonoscopy and sigmoidoscopy) had higher detection rates than stool-based tests for blood (gFOBT or FIT) for both advanced neoplasia (RR, 3.21; 95% CI, 2.38–4.32) and CRC (RR, 1.58; 95% CI, 0.97–2.56). The other meta-analysis showed that screening with sigmoidoscopy (alone or in combination with stool-based testing for blood) was more effective than stool-based testing for blood alone in detecting advanced adenoma and CRC. Specifically, the detection rates of advanced adenoma with sigmoidoscopy (alone or in combination with stool-based testing for blood) were on average about 7 times those with one-time gFOBT (RR, 7.23; 95% CI,
4.86–10.75) and about 4 times those with FIT (RR, 3.74; 95% CI, 3.03–4.62).

The results of two subsequent RCTs, conducted in Spain and Italy, were consistent with the observation of higher detection rates of advanced neoplasia and advanced adenoma with endoscopic techniques compared with stool-based tests for blood. In addition, the trial in Spain showed that sigmoidoscopy (simulated from colonoscopy data considering only lesions detected in the rectum and sigmoid colon) was better than one-time FIT in detecting distal neoplasia and that sigmoidoscopy and FIT had a similar performance in detecting advanced proximal neoplasia.

4.5.3 Cost–effectiveness

One systematic review on the cost–effectiveness of CRC screening compared the cost–effectiveness of endoscopic techniques with those of stool-based tests for blood. All of the models included consistently showed that both 10-yearly colonoscopy and 5-yearly sigmoidoscopy are more cost-effective than annual gFOBT. Six models found colonoscopy to be more cost-effective than annual FIT; whereas three models showed FIT to be more cost-effective than colonoscopy. Thirteen studies compared annual FIT with 5-yearly sigmoidoscopy, and all of them found FIT to be more effective and less costly.

4.6 Computed tomography colonography

The technology of computed tomography (CT) colonography provides two-dimensional and three-dimensional images of the colon with a non-invasive method. The colon needs to be prepared before the examination and distended during the examination with air or carbon dioxide inserted through a small, flexible catheter. Recently, faecal tagging has facilitated the development of colon preparation protocols with a reduced dose of a conventional cathartic agent or even without such an agent.

Based on four high-quality tandem studies of asymptomatic individuals, CT colonography is less sensitive than colonoscopy for the detection of small adenomas and polyps and has sensitivity nearly equivalent to that of colonoscopy for lesions 10 mm or larger, although there is variation between studies; this difference in sensitivity disappeared after adjustment for participation rate.

Three RCTs conducted in screening settings in Europe assessed participation rates and detection rates for lesions compared with other screening modalities, namely colonoscopy, sigmoidoscopy, and FIT. In the RCT in the Netherlands, compared with colonoscopy, CT colonography had an equivalent detection rate of cancer (0.5% for both), a lower detection rate of advanced adenomas (5.6% vs 8.2%), and a lower detection rate of adenomas 10 mm or larger (5.4% vs 6.3%). In one of the RCTs in Italy, the detection rates of advanced neoplasia were similar between CT colonography and sigmoidoscopy (5.1% vs 4.7%). In the RCT in Italy that compared CT colonography with FIT, CT colonography detected more CRC compared with FIT (0.5 vs 0.1) and more advanced adenomas (4.7% vs 1.6%) per participant.

In the analyses of three microsimulation models that all assumed 100% participation in screening, the estimated median reduction in the lifetime risk of dying from CRC associated with screening between age 50 years and age 75 years was similar between CT colonography every 5 years, annual FIT, annual FIT plus sigmoidoscopy every 10 years, and colonoscopy every 10 years.

Harms associated with CT colonography include perforation (for which the risk is very low compared with that of colonoscopy), radiation-induced cancer, the downstream effects of detection of extracolonic findings that warrant
further investigation, and the potential harms of follow-up colonoscopy after a positive test.

When the cost–effectiveness of CT colonography is considered relative to no screening, CT colonography screening consistently meets conventional criteria for cost–effectiveness. Comparative cost–effectiveness estimates are influenced by assumptions about CT colonography costs and participation rates, for which only limited information is available.

4.7 Participation in screening for colorectal cancer

4.7.1 Determinants of participation in colorectal cancer screening

Participation in screening for CRC is influenced by several factors that interact at the policy, organization, provider, and patient levels.

Insurance status and access to primary care are very important determinants of screening participation. Factors related to the organization of screening that have been shown to have an impact on participation include scheduling screening appointments, active call-and-recall systems, the amount of time required to perform screening, and the distance of the subject’s residence from the test provider. At the provider level, determinants of participation include the involvement of general practitioners, the use of informational material, time dedicated to preventive care, and knowledge about the effectiveness of the screening modalities. A specific barrier to participation in CRC screening in the general population is dislike of the available tests; also, there is evidence of differential participation by sex for stool-based tests for blood and endoscopy. In both men and women, participation tends to be lower for colonoscopy than for sigmoidoscopy or stool-based tests for blood.

The following have been identified as other factors that influence an individual’s likelihood of participating in CRC screening: lack of awareness of CRC and of the purposes of CRC screening; perceived susceptibility to CRC; lack of knowledge about screening effectiveness and procedures; fatalistic beliefs about CRC; negative attitudes towards preventive interventions; and perceptions about the relative weights of short-term inconveniences and long-term benefits. These factors are likely to mediate the association of socioeconomic status and education level with participation in CRC screening. Education level (including language barriers), access to care, and level of knowledge also contribute to the observed differences in participation between ethnic groups. Other factors that were found to strongly influence participation are anxiety associated with repeated testing and the level of support provided by the primary care physician and by a partner.

4.7.2 Approaches to increase participation in colorectal cancer screening

The introduction of population-based organized CRC screening programmes is the preferred option to increase participation in screening, by providing a context in which participation in screening and related assessments is not limited by financial or other organizational barriers, and therefore favours the reduction of inequities in screening access.

4.7.3 Interventions to increase participation in endoscopy screening

Eleven randomized trials have assessed interventions to increase participation in endoscopy screening (colonoscopy or sigmoidoscopy). Interventions such as patient navigation, management, coaching, or counselling (four RCTs) had a significant positive effect in some studies but not in others. Interventions in the form of informational brochures compared with usual care (two RCTs) or tailored invitation letters compared with standard invitation letters (four
RCTs) had a modest impact on increasing participation. A study assessing the use of advance notification letters found a positive impact on increasing participation. In one trial, the addition of a discussion with the general practitioner to providing an informational leaflet had no significant effect.

4.7.4 Interventions to increase participation in screening with stool-based tests for blood

More than 25 randomized trials to assess interventions to increase participation in screening with stool-based tests for blood have been conducted in asymptomatic individuals at average risk of CRC in high-income countries (Australia, Israel, and countries in North America and western Europe). The following interventions were all found to have a modest effect on increasing participation: advance notification letter; postal mailing of kits; written, telephone, and text message reminders; telephone contact with an advisor; invitation letter signed by a general practitioner; training of general practitioners focused on communication skills; and reminder letters sent to general practitioners.

4.7.5 Comparison of participation in two screening methods

Several comparative trials conducted in screening settings and two meta-analyses of such trials compared the participation rates with different screening methods, alone or in combination. Overall, participation rates were higher with FIT than with gFOBT, and the adoption of FIT in population-based programmes resulted in a reduction in disparities in access to CRC screening. In several RCTs, participation was lower with endoscopy screening than with stool-based tests for blood, although these comparisons were based on a single invitation round for stool-based tests for blood. In two trials, conducted in Australia and Italy, no increase in participation in CRC screening was observed when invitees where offered a choice of tests for CRC screening. A large population-based study found that the sequential offer of screening with sigmoidoscopy followed by FIT (i.e. people who refused sigmoidoscopy were invited for FIT) can increase overall participation, although participation was still lower than when FIT was offered alone.

4.8 Emerging techniques

Emerging technologies may be based on structural examinations that enable visual investigation of the entire colon, such as capsule colonoscopy, and examinations based on an analysis of biomarkers in stool, blood, or breath, such as volatile organic compounds (in breath), and of various protein, RNA, and DNA markers. Currently, three technologies have had at least some large-scale evaluation in populations at average risk compared with an established screening modality: the multitarget stool DNA test, capsule colonoscopy, and the methylated Septin 9 (mSEPT9) blood DNA test. All of these tests require a follow-up colonoscopy after a positive result, which entails the known reported adverse effects of colonoscopy (see Section 4.4).

4.8.1 Stool-based tests

Currently, one test is commercially available that is based in part on detection of mutations in tumour DNA found in stool: the multitarget stool DNA test. Specific targets of the multitarget stool DNA test include KRAS point mutations and aberrantly methylated NDRG4 and BMP3. The multitarget stool DNA test also includes an immunoassay component (see Section 4.3). The test result is determined to be positive or negative on the basis of a combined quantitative assessment of individual components of the test.
In a large screening population in which all individuals underwent screening with colonoscopy, FIT, and the multitarget stool DNA test, the multitarget stool DNA test detected significantly more cancers and advanced neoplasia compared with FIT, but showed a lower specificity for non-advanced lesions.

Modelling studies suggest that the multitarget stool DNA test is generally not cost-effective, because of high costs compared with simpler stool-based tests such as FIT.

4.8.2 Capsule colonoscopy

After extensive bowel preparation, the patient swallows a video capsule while wearing a data recorder. As the capsule transitions through the gastrointestinal tract, images are captured from two cameras, one at each end of the device. Patients found to have important lesions will require follow-up colonoscopy for further investigation. Capsule colonoscopy is approved for screening in the USA.

In a single large-scale tandem study with colonoscopy, capsule colonoscopy identified individuals with one or more polyps 6 mm or larger with a sensitivity of 81% (95% CI, 77–84%) and a specificity of 93% (95% CI, 91–95%).

4.8.3 Blood-based tests

There is currently a single commercially available test that is based on the detection of tumour DNA in blood: the mSEPT9 DNA test. As with the multitarget stool DNA test, the results provided are either positive or negative. The mSEPT9 DNA test is approved for screening in China and the USA.

In a large prospective study, the sensitivity of the mSEPT9 DNA test for CRC was 48.2% and the specificity was 91.5%, with a higher sensitivity for the detection of more advanced lesions.

4.9 Populations at high risk of colorectal cancer

Individuals at high risk of CRC fall into four categories of risk factors: genetic predisposition, family history of colorectal neoplasia, personal history of colorectal neoplasia, and medical conditions that predispose to CRC. Because individuals at high risk require more intensive testing, the term “surveillance” is generally used, and the term “screening” is reserved for asymptomatic populations at average risk. However, the evidence of a preventive effect of surveillance in these populations at high risk is at best limited.

4.9.1 Genetic predisposition

Genetic predisposition, which accounts for about 5% of all CRCs, can be subdivided into non-polyposis syndromes, adenomatous polyposis syndromes, and non-adenomatous polyposis syndromes. Non-polyposis syndromes include Lynch syndrome, which is caused by mismatch repair deficiency, and familial CRC, which is a genetically heterogeneous group. The most common adenomatous polyposis syndrome is familial adenomatous polyposis, which is caused by mutations in the APC gene, but there are also several rare genetically determined adenomatous polyposis syndromes. Non-adenomatous polyposis syndromes fall into two groups: (i) hamartomatous polyposis syndromes, which include Peutz–Jeghers syndrome, Cowden syndrome, and juvenile polyposis syndrome, and (ii) serrated polyposis syndrome.

Overall, there is little evidence on which to base decisions about surveillance strategies for individuals with genetic predisposition. For individuals with non-polyposis syndromes, colonoscopy is usually recommended every 1–2 years starting at age 20–25 years, and this is the only intervention in populations at high risk that has been proven to be effective. With familial adenomatous polyposis, the
surveillance strategy is dependent on the severity of the condition. For classic familial adenomatous polyposis, annual sigmoidoscopy is recommended from age 11 years, changing to colonoscopy when adenomas start to appear. For attenuated familial adenomatous polyposis, colonoscopy every 2 years is recommended from age 20 years, because proximal adenomas in the absence of distal lesions are common. For the rarer adenomatous polyposis syndromes, colonoscopy every 2 years is recommended every 2 years, from age 25 years for Peutz–Jeghers syndrome and from age 15 years for juvenile polyposis syndrome. No definitive guidance for surveillance is available for Cowden syndrome. For serrated polyposis syndrome, colonoscopy every 2 years from the time of diagnosis is recommended, but this strategy may be modified according to the histological classification of the lesions.

4.9.2 Family history of colorectal neoplasia

A family history of CRC is a well-established risk factor for developing CRC, but the relative importance of the underlying factors (i.e. genetic predisposition and shared environmental factors) is unclear. In people with a first-degree relative with CRC, the risk of CRC is approximately 2 times that in people with no such family history; the risk of CRC can increase up to 4-fold, depending on the number of relatives affected with CRC or advanced adenomas and the age at diagnosis.

Evidence is scarce for the effectiveness of surveillance and for the determination of surveillance intervals in individuals with a family history of CRC. Surveillance strategies, including surveillance intervals, vary by country and setting.

4.9.3 Personal history of colorectal neoplasia

Precancerous lesions detected at colonoscopy are removed as a preventive measure during screening. However, patients diagnosed with precancerous lesions have a higher risk of developing subsequent advanced adenomas or CRC, compared with people with no such findings. The magnitude of the risk and the recommended surveillance intervals depend largely on the characteristics of the lesions and the number of lesions, which are used to distinguish between patients with high-risk characteristics and those with low-risk characteristics.

Evidence on the effectiveness of surveillance after the detection of serrated lesions and polyps is limited. Recent guidelines recommend surveillance colonoscopy after 3 years after the detection and removal of high-risk sessile serrated polyps and lesions and traditional serrated adenomas, and after 5 years after the detection of low-risk sessile serrated polyps and lesions.

4.9.4 Medical conditions

Patients with certain medical conditions, including inflammatory bowel disease, acromegaly, ureterosigmoidostomy, and cystic fibrosis, have a significantly increased risk of CRC, and require an increased surveillance strategy compared with that for populations at average risk.
Screening for colorectal cancer is a multi-stage process, and the effectiveness of a screening programme will ultimately depend on the capacity and quality of the health-care system within which it takes place and on the resources available, as well as on other factors, including participation by the target population in the screening programme.

The following evaluations are based on a comprehensive review of the published scientific evidence. The majority of the randomized controlled trials and observational studies have been conducted: in middle- to high-income settings, where colorectal cancer incidence is generally high; in asymptomatic populations at average risk aged 50–70 years on average; and under conditions in which colorectal cancer screening, including subsequent follow-up and treatment, can be delivered with high quality. Extrapolation of the conclusions of this evaluation to different settings needs to take into account these and other context-related specificities.

The following evaluation statements on the level of evidence for the effects of the different colorectal cancer screening procedures refer to a setting without colorectal cancer screening as a comparator.

5.1 Guaiac faecal occult blood test

There is sufficient evidence that screening biennially with the guaiac faecal occult blood test (gFOBT) without rehydration reduces colorectal cancer mortality. This evaluation is supported by two randomized controlled trials, two large cohort studies with up to 11 screening rounds, and one population-based case–control study of both invitation to and attendance at gFOBT screening.

There is evidence suggesting lack of effect of screening biennially with gFOBT without rehydration in reducing colorectal cancer incidence. This evaluation is supported by three large randomized controlled trials of screening with gFOBT without rehydration and one Italian cohort study after 11 screening rounds.

There is sufficient evidence that the benefits of biennial screening with gFOBT without rehydration outweigh the harms when the screening programme can be delivered with high quality. This evaluation is based on sufficient evidence of reduced colorectal cancer mortality and on a gain in quality-adjusted life years, versus the short-term psychological harms of screening per se or of a positive test result, as well as the potential medical harms of follow-up colonoscopy after a positive test result.

There is sufficient evidence that screening annually or biennially with gFOBT of higher sensitivity reduces colorectal cancer mortality. This evaluation is supported by two randomized controlled trials of annual or biennial screening.
with gFOBT with rehydration with long follow-up, and a case–control study of biennial screening with gFOBT with rehydration.

There is limited evidence that screening annually or biennially with gFOBT of higher sensitivity reduces colorectal cancer incidence. This evaluation is supported by one randomized controlled trial of gFOBT with rehydration conducted in the USA showing similar reductions in colorectal cancer incidence after 11 rounds of annual screening and 6 rounds of biennial screening.

There is sufficient evidence that the benefits of annual or biennial screening with gFOBT of higher sensitivity outweigh the harms when the screening programme can be delivered with high quality. This evaluation is based on sufficient evidence of reduced colorectal cancer mortality, limited evidence of reduced colorectal cancer incidence, and a gain in quality-adjusted life years, versus the short-term psychological harms of screening per se or of a positive test result, as well as the medical harms of follow-up colonoscopy after a positive test result.

5.2 Faecal immunochemical test

There is sufficient evidence that biennial screening with the faecal immunochemical test (FIT) reduces colorectal cancer mortality. This evaluation is supported by several observational studies of both invitation to and attendance at biennial FIT screening, including three cohort studies, one of which included incidence-based mortality results after four rounds of biennial FIT screening, and one large ecological study after more than three rounds of biennial FIT screening. The evidence from four randomized controlled trials on screening with gFOBT and reduced colorectal cancer mortality, and the increased sensitivity and specificity of FIT compared with gFOBT for the detection of advanced adenomas and colorectal cancer, were also considered.

There is limited evidence that biennial screening with FIT reduces colorectal cancer incidence. This evaluation is supported by two cohort studies with up to five rounds of biennial FIT, and one ecological study in areas where biennial screening with FIT had been used for five rounds of screening, all showing a modest reduction in colorectal cancer incidence. The evidence from a randomized controlled trial showing a reduction in colorectal cancer incidence after biennial screening with gFOBT with higher sensitivity, and the increased sensitivity and specificity of FIT compared with gFOBT for the detection of advanced adenomas and colorectal cancer, were also considered.

There is sufficient evidence that the benefits of biennial screening with FIT outweigh the harms when the screening programme can be delivered with high quality. This evaluation is based on sufficient evidence of reduced colorectal cancer mortality and limited evidence of reduced colorectal cancer incidence, and a gain in quality-adjusted life years, versus the short-term psychological harms of screening per se or of a positive test result observed with similar screening procedures (such as gFOBT), as well as the potential medical harms of follow-up colonoscopy after a positive test result.

The Working Group is aware that there is a large variety of qualitative and quantitative FIT tests available, with wide ranges of sensitivity and specificity. The balance of benefits and harms will depend on the cut-off level for positivity.

5.3 Flexible sigmoidoscopy

There is sufficient evidence that a single screening with flexible sigmoidoscopy reduces colorectal cancer mortality. This evaluation is supported by four randomized controlled trials and corroborated by several observational studies in screening settings. No conclusion can be drawn about the added benefit of subsequent
screenings with flexible sigmoidoscopy on colorectal cancer mortality.

There is sufficient evidence that a single screening with flexible sigmoidoscopy reduces colorectal cancer incidence. This evaluation is supported by four randomized controlled trials and corroborated by several case–control studies in screening settings. No conclusion can be drawn about the added benefit of subsequent screenings with flexible sigmoidoscopy on colorectal cancer incidence.

There is sufficient evidence that a single screening with flexible sigmoidoscopy reduces colorectal cancer incidence. This evaluation is supported by four randomized controlled trials and corroborated by several case–control studies in screening settings. No conclusion can be drawn about the added benefit of subsequent screenings with flexible sigmoidoscopy on colorectal cancer incidence.

There is sufficient evidence that the benefits of a single screening with flexible sigmoidoscopy outweigh the harms when the screening programme can be delivered with high quality. This evaluation is based on sufficient evidence of reduced colorectal cancer incidence and mortality and on a gain in quality-adjusted life years, versus the short-term psychological harms of screening per se or of a positive test result, the infrequent procedural harms of sigmoidoscopy, and the medical harms of follow-up colonoscopy after a positive test result.

5.4 Colonoscopy

There is sufficient evidence that a single screening with colonoscopy reduces colorectal cancer mortality. No conclusion can be drawn about the added benefit of subsequent screenings with colonoscopy on colorectal cancer mortality.

There is sufficient evidence that a single screening with colonoscopy reduces colorectal cancer incidence. No conclusion can be drawn about the added benefit of subsequent screenings with colonoscopy on colorectal cancer incidence.

These evaluations are supported by the evidence from randomized controlled trials on screening with flexible sigmoidoscopy: given the close similarity between the two procedures, a properly done full colonoscopy, by definition, includes a sigmoidoscopy, and therefore it is inferred that colonoscopy will be at least as good as flexible sigmoidoscopy at detecting advanced adenomas and colorectal cancer. In addition, three observational studies and a meta-analysis of observational studies reported a reduced colorectal cancer incidence or mortality, and chance, bias, and confounding can be ruled out with reasonable confidence.

There is sufficient evidence that the benefits of a single screening with colonoscopy outweigh the harms when the screening programme can be delivered with high quality. In reaching this evaluation, the Working Group considered the evidence of reduced colorectal cancer incidence and mortality and a gain in quality-adjusted life years, versus harms such as bleeding and perforations, as well as the psychological harms of screening per se or of a positive test result.

A minority of the Working Group members considered that the evidence was limited because of the variability and the related limited accuracy of the effect estimates, the associated harms of colonoscopy, and the inherent limitations in extrapolating from data of screening with flexible sigmoidoscopy.

5.5 Computed tomography colonography

There is limited evidence that a single screening with computed tomography (CT) colonography reduces colorectal cancer incidence and mortality. No conclusion can be drawn about the added benefit of subsequent screening with CT colonography on colorectal cancer incidence and mortality.

In reaching this evaluation, the Working Group considered that: CT colonography has a very high sensitivity and high specificity, in particular a high sensitivity for the detection of advanced neoplasia (i.e. large adenomas and cancerous lesions), which has been shown to be associated with increased risk of developing colorectal cancer; CT colonography is comparable to a stool-based test in that a positive result
requires referral for colonoscopy; however, there are currently no randomized controlled trials or observational studies on the effect of CT colonography on colorectal cancer incidence or mortality in a screening setting.

A minority of the Working Group members considered that the evidence was inadequate, because of: the lack of randomized controlled trials or observational studies with incidence and mortality as end-points; the wide extrapolation needed from the known detection rates of lesions to an expected reduction in colorectal cancer incidence and mortality in a screening setting; the lack of studies with repeated CT colonography screening; and the fact that only detection rates and test performance in terms of sensitivity and specificity were available.

There is inadequate evidence that the benefits of a single screening with CT colonography outweigh the harms. This evaluation is based on the lack of direct evidence for a beneficial effect of screening with CT colonography in reducing colorectal cancer incidence or mortality, versus the harms of ionizing radiation, the uncertain harms and benefits of extracolonic findings, and the uncertainty when quantitative data of beneficial and adverse effects are lacking.
A Working Group of 23 independent experts from 15 countries, convened by the International Agency for Research on Cancer (IARC) in November 2017, reviewed the scientific evidence and assessed the cancer-preventive and adverse effects of various methods of screening for colorectal cancer. Colorectal cancer is the third most common cancer in men and the second most common in women worldwide, and represents more than 10% of the global cancer burden.

This publication provides evidence-based evaluations of the effectiveness of colorectal cancer screening in reducing colorectal cancer incidence and mortality. The Working Group also reviewed the body of evidence on the comparison of endoscopic and stool-based techniques, on the determinants of participation in screening programmes, and on the most mature emerging techniques that may be alternatives to current practices for colorectal cancer screening, as well as presenting the different categories of high-risk populations and the surveillance strategies for such individuals.
